Low activity  $\alpha$ -galactosidase A leads to the accumulation of neutral GSLs with terminal  $\alpha$ -galactosyl residues. There is widespread accumulation of globotriaosylceramide or ceramide trihexoside (CTH) in the lysosomes of vascular endothelial and smooth muscle cells, and in the epithelial and perithelial cells of most organs. CTH levels in hemizygote males may be 30–300 times that in normals (434,556). Galabiosylceramide also reaches high levels in FD patients, but in a tissue-specific manner. Affected tissues include kidney, pancreas, right heart, lung, dehiscent renal tubule cells, and spinal and sympathetic ganglia (557). Blood groups B and B1 GSLs that inhibit blood group B agglutination accumulate in patients with blood groups B and AB. GSLs are degraded in a stepwise fashion by a family of specific exoglycosidases found predominantly in lysosomes. These exoglycosidases are glycoproteins with optimal catalytic activity at acidic pH.  $\alpha$ -Galactosidase A deficiency causes FD, whereas  $\alpha$ -galactosaminidase B deficiency causes a type of neuroaxonal dystrophy called Schindler disease (397,558).  $\alpha$ -Galactosidase A is a protein of ~101 kDa. Affected males have normal plasma  $\alpha$ -galactosidase A activities, but deficient peripheral leukocyte  $\alpha$ -galactosidase A. Plasma GSLs are synthesized in the liver and incorporated into lipoproteins in the systemic circulation. Hepatic enlargement/dysfunction is not a feature of FD, although storage occurs in hepatocytes. Twenty-five percent of the plasma GSL pool is newly synthesized each day, and a portion is derived from the turnover of senescent red blood cells. The rate of GSL exchange between plasma and that found in cell membrane has not been determined. This has to be taken into account while measuring changes in plasma CTH

and while trying to correlate it to clinical response to therapy and/or disease progression. It has been suggested that the changes in urinary CTH may be a more sensitive and specific measure of tissue and body CTH burden (559).

The mechanism by which accumulating GSLs cause multiorgan disease is not completely understood. It cannot be explained by pure substrate storage (560). The mechanical deposition of storage material in blood vessels was believed to lead to decreased blood supply with consequent organ dysfunction. Many secondary biochemical processes may be involved in the pathogenesis of FD. Compromised energy metabolism occurs in vitro and in vivo, and altered lipid composition of membranes can lead to abnormalities in the trafficking and sorting of raft-associated proteins, leading to cellular and organ dysfunctions (561). In the brain, the pathogenesis of FD vasculopathy may be associated with endothelial dysfunction, cerebral hyper-perfusion, and a prothrombotic state with increased production of ROS. These abnormalities are further modified by genetic and possibly other vascular risk factors.

#### 104.13.5 Genetics

FD is panethnic. The  $\alpha$ -galactosidase A protein is encoded by a 12-kb gene mapped to the long arm of the X chromosome (Xq22.1). The gene is composed of seven exons. FD is caused by a wide variety of molecular defects: 57% of disease alleles are missense mutations, 18% partial gene deletions, 11% nonsense mutations, 6% insertions, and 6% RNA processing defects due to faulty splicing. Mutations have been found in all seven exons (56). Most enzyme mutations are private (i.e. confined to a single Fabry pedigree), but several occur in multiple, unrelated families (559). Many of the latter occur at CpG islands that are mutation hotspots because of the deamination of methylcytosine to thymidine. N215S, a common mutation in atypical asymptomatic or mildly affected patients with only cardiac involvement does not occur at these CpG dinucleotide hotspots. Efforts to establish genotype-phenotype correlations are limited, since the majority of the mutations are private and because the clinical phenotype, age of onset, and course of FD are very variable, even within the same family. Attempts to predict the phenotype require more extensive clinical information from unrelated patients with the same genotype. In addition, attempts to predict the clinical phenotype on the basis of the type or location of a molecular lesion are premature. For example, several mutations, N215S, Q279E, M296V, and R301Q, located in exons 5 and 6 lead to atypical or mildly affected cases. Nearby missense mutations, however, such as S297F (adjacent to M296V) result in a severe form of the disease. Patients from unrelated families with the G328R, R301Q, and R112H have presented with the classic disease phenotype in one family and mild disease in another (56).

The diagnosis of FD should prompt screening of family members. Although the disease presents in hemizygous males, the condition can be expressed in obligate female carriers because of nonrandom, random X chromosome inactivation.

### 104.13.6 Diagnosis/Testing

The diagnosis is made once low  $\alpha$ -galactosidase A activity is established in leukocytes or cultured skin fibroblasts. Enzyme activity is not a reliable way to distinguish affected hemizygous males from unaffected obligate carrier females. Genetic analysis is required for the diagnosis of female heterozygotes with FD. With a positive family history, carrier diagnosis is best confirmed by molecular testing in cases in which the defect is known or by linkage analysis when the specific gene defect is unknown. Carrier detection has been established in the past by the analysis of urinary sediments, which show elevations in the total glycolipid fraction, and elevated CTH and digalactosylceramide levels. Measurement of CTH may be used as a diagnostic tool in women with suspected FD. In men, urine CTH could be used to screen for FD. In men with suspected FD, diagnosis should be made by measuring enzyme activity (562). FD can be detected prenatally by the analysis of enzyme activity and the determination of the sex of the fetus, or by DNA analysis of CVSs or cultured amniocytes. Recognized MRI abnormalities in the brains of patients with FD include the consequences of infarction and hemorrhage, nonspecific white and gray matter lesions, vascular anomalies, in particular dolicho-ectasia, and a characteristic appearance of the posterior thalamus. Analysis of MRI findings in patients indicates that most patients have abnormal scans, most commonly cerebral white matter lesions. The number of the lesions increases with the patient's age and decreases in response to ERT (563).

### 104.13.7 Animal Models

A mouse model for FD was generated by the disruption of the  $\alpha$ -galactosidase A gene in mouse ES cells. Tissues from these mice had no detectable  $\alpha$ -galactosidase A activity (564) and elevated levels of globotriaosylceramide (GB3). They, however, were not affected clinically. They do, however, provide an excellent model to test the efficacy of different therapies.

### 104.13.8 Treatment

The management of patients with FD requires a multidisciplinary approach, because of the multiorgan nature of the disease. Historically, the treatment of FD has been symptomatic and palliative, and was based on the use of antihypertensives, phenytoin, gabapentin, and carbamazepine for the treatment of chronic neuropathic pain and ticlopidine for the prothrombotic state

that characterizes the disease. In the 1980s, a trial with  $\alpha$ -galactosidase A enzyme purified from human plasma demonstrated that this enzyme was effective in depleting the circulating GB3, but clinical application was limited due to the difficulty in producing large amounts of the enzyme. More than 20 years after purified enzyme infusion, a patient with the cardiac variant of FD was treated with galactose infusions, based on the principle of chaperon-mediated therapy. After 3 months of therapy, there was an improvement in cardiac contractility and a reduction in left ventricular mass (LVM), but the long-term benefits remain to be determined. Recently, ERT with recombinant human  $\alpha$ -galactosidase A was proposed as a specific treatment for FD. Early trials demonstrated the safety of ERT, as well as the efficacy in reducing GB3 storage in several organs and tissues, and in improving the signs and symptoms of the disease and the quality of life. The response of the neuropathic pain has been questionable. Longer follow-up is necessary to fully evaluate these treatments. Treatment with ERT should start as soon as clinical signs and symptoms appear. Some suggest that ERT should be given to all hemizygous male patients to prevent organ damage or to slow down the progression of preexisting severe organ damage (565). Kidney transplantation and dialysis have been necessary for some patients. To date, ERT is the only available FDA-approved therapy for FD. Two different forms of  $\alpha$ -galactosidase A ERT are available for treatment of FD: one genetically engineered in human cell lines (agalsidase  $\alpha$ , Replagal, Shire) and the other produced in a Chinese hamster ovary cell line (agalsidase  $\beta$ , Fabrazyme, Genzyme) (566). Studies with both preparations have described a reduction in plasma, urinary sediment, and tissue levels of GB3. Some reports support clinical benefit from ERT with a decrease in the frequency of pain crises and a reduction in left ventricular mass, and the improvement or stabilization of renal function, particularly when treatment is started at an early stage before irreversible tissue damage has taken place (567). There is considerable variation in the response to ERT due to heterogeneous phenotypic expression in patients of all ages and the lack of clear guidelines about when and which patients to treat. Five randomized controlled studies comparing agalsidase  $\alpha$  and  $\beta$  with both preparations administered as infusions every fortnight, concluded that aggregate results and differences were nonsignificant (568). ERT is entirely safe. In the first 3 months of treatment, headaches, hot flushes, and elevated temperature may be experienced as side effects. Patients may develop nausea and vomiting, flushing, and chills. The therapy has to be continued for a patient's entire lifetime. Costs are substantial, amounting to \$350,000/patient/year. Initial clinical trials showed great promise, but long-term effects are not as robust as initially anticipated (569). Information about long-term treatment with ERT is culled from cohort studies derived from patient registries, or from open extension studies of phase III trials.

Patients benefit to a variable extent from ERT. Whether treatment prevents organ manifestations in early symptomatic/presymptomatic patients and reduces mortality is still debatable (544). Controlled trials are needed to test whether treating children early will improve the neurological outcome. Studies with symptomatic female carriers are needed as are investigations of optimal time for early initiation of ERT to prevent irreversible organ damage (570). Large studies are needed to demonstrate the benefits of using concomitant angiotensin-converting enzyme inhibitors for their renoprotective properties or antiplatelet aggregating agents for primary and secondary stroke prevention in affected individuals, whether receiving ERT or not (568). There is no evidence that statins are effective in ameliorating vasculopathic changes in FD (571). ERT does not normalize the function of the PNS although neuropathic pain, sweating, and heat intolerance are somewhat improved (572). The available evidence supporting ERT in patients with renal disease (573,574) is not compelling with regard to outcomes, course of cardiomyopathy, or survival. That being said, ERT can be considered on an individual basis, particularly if the treatment is instituted early in the course of renal disease (575). Management of cardiovascular symptoms and the prevention of complications still rely on conventional pharmacologic and device-based therapies. Advanced cardiac disease may require permanent pacemakers and cardiac transplant. There is improvement of left ventricular mass and systolic function in patients with FD after 12 months of ERT. Many of the patients studied, however, are relatively young and have mild cardiac abnormalities (576). There are reports of cardiac damage present in older patients with FD, despite the use of ERT. The role and timing of ERT are still controversial in the prevention and amelioration of cardiac complications of FD (577). Beneficial effects of ERT on gastrointestinal symptoms in FD disease have been reported (578).

Galactose at subinhibitory doses to the enzyme in the presence of some mutations may prove to be beneficial as well. Currently, there are also investigations into other therapeutic approaches, such as SRT and enzyme enhancement with pharmacologic chaperones, which may have therapeutic value (568). 1-Deoxygalactonojirimycin is a potent inhibitor of  $\alpha$ -galactosidase A. It is an effective active site-specific chaperone and increases the residual enzyme activity in cultured fibroblasts and lymphoblasts established from Fabry patients with a variety of missense mutations. Oral administration of DGJ to transgenic mice expressing a mutant form of human  $\alpha$ -galactosidase A yielded higher  $\alpha$ -galactosidase A activity in major tissues. DGJ may be effective for patients who have missense mutations that primarily lead to misfolding of the mutant protein. DGJ could also be useful as an adjunct therapy with ERT for patients whose residual enzyme activity cannot be increased by DGJ alone to a level that reverses disease development. This

would provide undeniable advantages of convenience, cost savings, and ease of accessibility by the drug to tissues, including the CNS (579).

## 104.14 NEURONAL CEROID LIPOFUSCINOSIS OR BATTEN DISEASE

### 104.14.1 Introduction

The neuronal ceroid lipofuscinosis (NCL) or Batten disease are a group of clinically and genetically heterogeneous neurodegenerative diseases affecting predominantly the pediatric population with a worldwide incidence of 1 in 12,500 live births. Clinical features are progressive, which include visual loss, cognitive and motor deterioration, seizures, and early death (367). The NCLs were thought to comprise 10 variants termed CLN1-10, until recently when CLN9 was found to be a juvenile variant of CLN5 (580,581). A genetic origin with autosomal recessive inheritance is attributed to all of these variants except for the adult variant previously classified as CLN4, but now we know that autosomal recessive mutations in the *CLN6* gene accounts for some type A Kufs patients, and that mutations in cathepsin F or CLN13 account for some adult Kufs, B variants. CLN4/Kufs disease has both autosomal dominant and recessive patterns of inheritance. Also, two other recently described variants include mutations in progranulin or CLN11 accounting for some adult cases, and ATP13A2 or CLN12. Variants are grouped by the gene that bears the mutation and the age of onset of disease symptoms. Eleven genes have been identified and account for the many pediatric and adult clinical phenotypes: CLN1/protein palmitoyl thioesterase or PPT1, CLN2/tripeptidyl peptidase or TTP1, CLN3/battenin, CLN5, CLN6, CLN7, CLN8/EPMR, and CLN10, CLN11, CLN12, and CLN13. The clinical types are (1) congenital (CLN10), (2) classical infantile (INCL/CLN1), (3) classical late infantile (LINCL (late infantile neuronal ceroid lipofuscinosis)/CLN2), (4) variant late infantile/early juvenile Finnish (CLN5), (5) variant late infantile, Costa Rican or Portuguese, Pakistani, and others (CLN6), (6) classical juvenile (JNCL/CLN3), (7) epilepsy with mental retardation/LINCL (EPMR/CLN8), (8) Turkish variant late infantile (tLINCL/CLN7), CLN12 (juvenile Kufor-Raheb/CLN12 or ATP13A2), and (9) adult-onset variants recessively inherited (261,582). Recently, some cases of autosomal recessive Kufs type A disease were found to be caused by mutations in the *CLN6* gene (583) and adult Kufs B were found to be caused by CLN13 or Cathepsin F. Turkish vLINCL was previously believed to represent a distinct clinical and genetic entity, CLN7 (584), but is now known to be genetically heterogeneous with at least three underlying genes. These include *CLN6* (585), *CLN8* (586), and the *CLN7/MFSD8* gene, the identification of which occurred in Turkish patients (587). Autofluorescent

storage material accumulation is a feature common to all NCLs, and is generally a combination of proteins, proteolipids, and metals (588). The main type of storage material is subunit C of mitochondrial adenosine triphosphate (ATP) synthase which accumulates in CLN2, CLN3, CLN5, CLN6, CLN7, and CLN8 disease (440). In CLN1 disease and congenital NCL (CLN10 disease), there is the accumulation of sphingolipid-activating proteins (saposins A and D) (589,590).

The majority of variants manifest neuronal and photoreceptor-programmed cell death. Neuronal loss is viewed by CT and MRI as cerebral and cerebellar cortical atrophy (Figure 104-12A–B). Apoptosis of photoreceptor cells is documented as low amplitude a and b waves by ERG. Ultrastructural features by electron microscopy include vacuolated lymphocytes, granular osmiophilic deposits (GRODS) in INCL, curvilinear bodies in LINCL, curvilinear and/or fingerprint-like inclusions in juvenile neuronal ceroid lipofuscinosis (JNCL), and combinations of them in the others. These inclusions are present in multiple cell types including liver, muscle, conjunctiva, and of course, neurons.

A deluge of new information has materialized over the past decade regarding the genetics, molecular and cell biology, and biochemistry of these diseases. PPT1, TPP1, and cathepsin D are soluble lysosomal enzymes with known function, although these variants are not typical lysosomal storage diseases.

CLN6 and CLN8 are ER-resident proteins, and CLN3 is a protein that traffics between Golgi, early recycling endosomes, and LRs at the cell surface. CLN3, CLN6, and CLN8 are hydrophobic membrane proteins. CLN5 protein localization has been debated but the current consensus is of a predominantly soluble protein that is trafficked to the lysosome (591). CLN7/MFSD8 is a member of the major facilitator superfamily of proteins that act as transporters of small solutes by chemiosmotic gradients. CLN7 protein localizes to the lysosome

and is thought to act as a novel lysosomal transporter (587,592).

Both naturally occurring and engineered animal models are described in mice, dogs, cats, sheep, cattle, pigs, and birds. The *nclf* and *mnd* mice are naturally occurring CLN6 and CLN8 variants, respectively. The New Zealand South Hampshire sheep are excellent models for CLN6. Transgenic mouse models for CLN1, 2, 3, 5, 6, 7, 8, and 10 variants are also available.

Diagnosis is based on clinical course and supplemented by tell-tale neuroradiologic and electrophysiologic studies and established by the corresponding enzymatic (PPT1, TPP1, or cathepsin D activity in CLN1/CLN2 and CLN10, respectively) or DNA-based laboratory tests. Skin biopsy electron microscopy remains as a mainstay of our diagnostic tools, especially when it comes to the delineation of new clinical variants not caused by any of the known gene defects. Current studies also highlight the role of gene mapping as a useful diagnostic tool especially in atypical NCL cases (593). As with most genetic diseases, prenatal diagnosis is possible through chorionic villus sampling, followed by enzyme testing, mutation analysis, or identification of inclusions by electron microscopy. For families at risk with a known predetermined mutation, preimplantation diagnosis is theoretically possible on day 4–5 after conception, but the authors are unaware of this having ever taken place. Treatment options no longer include just supportive antiepileptic, nutritional, and physical measures, but now comprise targeted approaches in light of newly delineated biochemical and cell biological processes. Examples include cysteamine or Cystagon in INCL, and Flupirtine in INCL, LINCL, JNCL, and CLN6 variants (288). Immunosuppression with mycophenolate was shown to be beneficial in mice models of juvenile NCL (594) and a trial is being currently planned for JNCL patients. Preclinical trials in ERT (595,596), gene therapy (597,598), and stem cell therapy (599) are

**FIGURE 104-12** CLN13 disease, juvenile variant MRI. (a) Sagittal section showing gaping sulci and cerebral and cerebellar atrophy. (b) Coronal section showing altered T2 signal of thalami and basal ganglia.

ongoing for CLN1, CLN2, and CLN10 diseases. Stem cell replacement is actively being pursued as potential therapy for CLN1 and CLN2 diseases.

### 104.14.2 History and Terminology

In 1826, Stengel described the first JNCL cases, followed by clinical and pathological descriptions by Batten, Mayou, Spielmeyer, Vogt, and Sjögren (301,600–602). The *CLN3* gene responsible for JNCL was identified in 1995 (603). First reports of the late infantile form (LINCL) were made by Jansky and Bielchowski in 1908 and 1913 (275). LINCL and JNCL were previously known as Batten disease. Batten disease now refers to all variants. The adult form or Kufs disease, an early-onset dementia with seizures and absence of visual findings, was described in 1925 (403). There are sporadic and familial reports of Adult Neuronal Ceroid Lipofuscinosis (ANCL) reported, with some families suggesting a dominant mode of inheritance. The *CLN4* genes responsible for the adult disease have not been identified. The term neuronal ceroid lipofuscinosis was introduced by Zeman and Dyken in 1969 to describe the autofluorescent, waxy, and dusky lipid deposits seen in neuronal endosomes (604). The infantile form or INCL was first described by Hagberg, followed by Haltia and Santavuori in 1973 (484,605,606). The *CLN3* gene was mapped in 1990 (607), followed by the *CLN1* gene (608,609), and the *CLN2* gene responsible for LINCL (610,611). Various other variant late infantile forms and early juvenile forms with defects in the *CLN5*, *CLN6*, *CLN7*, and *CLN8* genes are now recognized (207,293,612–614). The terminology is confusing. The terms INCL, LINCL, JNCL, and ANCL were chosen to classify these diseases according to the age of onset. This no longer holds true for all the types described. Discovery of the more recent genes and better ascertainment of atypical cases with a variable age of onset muddled the story somewhat. Different defects in one gene can manifest with variable clinical course and more than one age of onset. A genetic reference to the gene defect may be best for the moment (CLN1-, CLN2-, CLN3-, CLN5-, CLN6-, CLN7-, CLN8- and CLN-10).

Naming the genes *CLN* genes as opposed to *NCL* genes is regrettable, because yeast cyclin genes are also called *CLN* genes in the scientific literature. Changing matters at this juncture will make things even more difficult. In the United States, all forms are referred to as Batten disease. Although historically incorrect, it is a practical choice easy for all to remember and pronounce. The term Batten disease is universally recognized and accepted by families, physicians, private foundations, and government agencies in the United States. Some of our European colleagues on the Continent disagree. In view of the current genetic, allelic, and phenotypic heterogeneity of NCL, an axial nomenclature system, similar to that used for the epilepsies and

mental disorders, has been proposed that is acceptable to all involved:

Axis 1: Affected gene—*CLN1*, *CLN2*, *CLN3*, etc.

Axis 2: Mutation diagnosis

Axis 3: Biochemical phenotype—PPT1/TPP1/CTSD deficiency

Axis 4: Clinical phenotype—Congenital, infantile, late infantile, juvenile, adult onset, etc.

Axis 5: Ultrastructural features—For example, GROD, should include the specimen type studied (e.g. skin, conjunctiva)

Axis 6: Functionality—describes the current level of functioning using a universal scoring system, (Hamburg scales and the Unified Batten Disease Rating Scale)

Axis 7: Other remarks—relevant to the clinical condition; for example, stressors that may affect disease progression

### 104.14.3 Major Batten or Neuronal Ceroid Lipofuscinosis Syndromes

**104.14.3.1 INCL (CLN1 Disease, Infantile Variant, INCL, Haltia–Santavuori Variant, Palmitoyl-Protein Thioesterase or PPT1-Deficient).** INCL is caused by a deficiency in palmitoyl-protein thioesterase or PPT1, whose function is to remove fatty acids attached in thioester linkages to cysteine residues in proteins (615). The first description of this disease was by Hagberg (484). A more comprehensive clinical and pathological description of this autosomal recessive disorder was supplied by Haltia and Santavuori (606,616,617).

**104.14.3.1.1 Clinical Description.** Most cases of CLN1 disease in the Finnish population have an infantile onset. Only 50% of the CLN1 cases have an infantile onset in the United States. The other cases have late infantile, juvenile, or adult onset. Typical onset is in infancy but can be delayed until adulthood. Development is normal until 10–18 months of age, with slowed head growth beginning at 5 months. Developmental stagnation occurs and fine motor skills are impaired and hypotonia and ataxia follow. Patients become microcephalic. Visual impairment is present at 1 year of age and leads to blindness at the age of 2 years. Optic atrophy, thinned retinal vessels, and a discolored brownish macula are present. Myoclonic jerks begin after year one, with many developing generalized seizures. Rett-like hand knitting movements are observed early on but vanish by 2 years. At 3 years, children are nonambulatory, spastic, hypotonic, and irritable. Severe flexion contractures, acne, hirsutism, and precocious puberty often develop. Death ensues between the ages of 7 and 13 years. Atypical cases may have a delayed age of onset to 4 years. An adolescent-onset form reminiscent of the classical juvenile variant occurs in patients of Scottish descent (618). A single report describes two families with adult onset and mild course.

**104.14.3.1.2 Clinical Diagnostic Tests.** Measurement of PPT1 enzyme activity in leukocytes delivers the diagnosis (287). Enzyme activity can be measured from a dried blood spot on filter paper, or from cultured fibroblasts. Enzyme activity less than 5% of normal is diagnostic for INCL. DNA diagnostics is offered by specialized laboratories. Electron microscopic examination of skin shows characteristic membrane-bound GRODS seen in endothelial or perithelial cells and nerve cells of the submucosal myenteric nerve plexus. The EEG can be normal, and then gradually worsens. Lack of sleep spindles and the absence of the attenuation in amplitude, usually seen with eye opening, occurs by 16–24 months. The EEG becomes isoelectric by age 3 years. ERG, VEPs, and SEPs are abnormal, but seldom resorted to. The ERG is abnormal with cones affected before rods. CT and MRI findings include signal loss in the thalami, cerebral atrophy, and thinned periventricular rims early on. Postmortem MRI T2-weighted images reveal hypointensity of gray with respect to white matter. Prenatal diagnosis has been accomplished using CVSs at 11 weeks, and amniocytes at 16–18 weeks: EM or ultrastructural studies show GRODS and PPT1 enzyme assay and/or DNA analysis confirm the result. EM remains incredibly useful, when enzymatic diagnosis is not available, or equivocal, or knowledge of the family mutation is missing. All three diagnostic modalities should be used. The diagnosis of a normal or carrier fetus should be confirmed at birth by analysis of cord blood.

**104.14.3.1.3 Pathology.** Initial pathological events include progressive thalamic neuron loss and localized astrogliosis. Cortical neuronal loss follows thalamic neuron loss (618). Subtotal loss of neurons occurs by 4 years with significant decrease in brain weight. Betz cells and neurons of the hippocampal CA1 and CA4 sectors are preserved and reactive astrocytes become progressively more prominent. GRODS in neurons and macrophages are seen at 8 weeks of gestation. There is extensive gliosis. The brainstem and basal ganglia are also involved. The anterior horn cells demonstrate storage. Storage granules are seen in all tissues yet tissue destruction only occurs in the brain and retina (368,619). In addition to the involvement of the forebrain, there is significant hindbrain pathology manifested by widespread degeneration of cerebellar afferents and efferents and the death of Purkinje cells progressing from anterior to posterior cerebellar lobes, followed by granular cell layer degeneration (620). There is also prominent cerebellar astrocyte activation, gliosis Purkinje cell deficit, and GRODS accumulation (621).

**104.14.3.1.4 Biochemistry, Cell Biology and Pathophysiology.** Loss of function of PPT1, which removes long-chain fatty acids attached in thioester linkage to proteins, is the biochemical basis for this disorder. The severity of CLN1 disease correlates with residual PPT1 activity (622–624). The fatty acylated-cysteine-residue containing proteins found at the inner PM leaflet are

normally subjected to acylation and deacylation. Loss of this may impact protein–protein and protein–lipid membrane interactions. S-acylated protein degradation in lysosomes can also be impaired in CLN1 disease, which, like most of the NCLs, differs from other storage diseases because what accumulates in the cell has no apparent link to the actual defect, and may be a secondary occurrence. PPT1 is taken up via mannose-6-phosphate receptors into lysosomes, but is also activated at neutral and basic pH, and hence must function elsewhere in the cell. PPT1 also colocalizes with synaptophysin to presynaptic vesicles in neurons. Sphingolipid activator proteins A and D accumulate in storage cytosomes (218). Brain sphingomyelin and other phospholipids are decreased in INCL brain. Rates of apoptosis are increased in lymphocytes, cultured lymphoblasts, fibroblasts, and PPT1-deficient neurons (527). Increased apoptosis is a common theme in neurodegenerative disorders. The defect in deacylation of S-acylated proteins and the increased apoptosis of PPT1-deficient cells and neurons have led to specific therapeutic approaches (see “Management and Treatment” section).

**104.14.3.1.5 Genetics.** To date, there are 48 or more known mutations in the *CLN1* gene reported in the United States, Europe, China, and the Middle East. These are not limited to exons, as they affect introns, the promoter, and the 3′ untranslated region. (<http://www.ucl.ac.uk/ncl/cln1.shtml>). Pathogenic mutations include insertions, deletions, aberrant splicing, and frameshift and initiation defects.

**104.14.3.1.6 Management and Treatment.** Supportive therapies are important. Chloral hydrate is used for sleep disturbances. Baclofen and benzodiazepine treat irritability, sleep disturbances, spasticity, and rigidity. Topiramate valproic acid, piracetam, and benzodiazepine derivatives are used for seizures and pain. Physical therapy delays the onset of contractures. Virally mediated *CLN1* gene delivery clears storage and symptoms of a neurologically impaired mouse model. A recent and important finding is that very early (pre-symptomatic) therapy provides better results. Enzyme replacement is also a theoretical possibility and may be achieved via direct injection into the brain or CSF shunt. Stem cell therapy trials in a mouse model for *CLN1* are underway. Attempts at BM transplants have not been successful even when performed at preclinical stages of the disease. Drugs that allow read-through of mutations that introduce premature stops in PPT1 DNA are being considered. Drugs that help the mutated protein to fold correctly and regain activity, or escape degradation by increasing the amount of chaperones, such as Hsp70, are also under investigation. This approach is likely to be most suitable for proteins containing a missense mutation. Clinical trials using cystagon (cysteamine), a drug that breaks down the storage material in combination with Mucormyst, which may decrease apoptosis, are ongoing. Flupirtine is an oral antiapoptotic drug with

analgesic, muscle relaxant, and weak anticonvulsant properties that protect PPT1-deficient cells from apoptosis. It is an approved analgesic and antispasmodic in Europe. Its clinical efficacy in INCL is unknown, but anecdotal reports suggest a positive effect on EEG, spasticity, and seizure control.

#### 104.14.4 LINCL or Late Infantile Batten Disease (CLN2 Disease, Late Infantile Variant, Jansky–Bielchowski, Tripeptidyl Peptidase, or TPP1-Deficient)

LINCL is caused by defects in the gene for a lysosomal tripeptidyl peptidase (TPP1; CLN2) (611). First reports were by Jansky in 1908, then Bielchowski in 1913. It occurs in European, Middle-Eastern, Chinese, Pakistani, and Indian patients. It is the second most common form of Batten disease in the United States, although the total number of cases at any point in time is less than 500 making it an orphan disease according to FDA guidelines. A large number of cases originate from Europe. Atypical cases with juvenile onset and a protracted course have been reported (i.e. CLN2 disease, Juvenile variant).

**104.14.4.1 Clinical Description.** Late infantile phenotype: The disease presents with seizures and ataxia between the ages of 2.5 and 3.5 years. After 6 months, vision, motor, and cognitive skills deteriorate. Patients become blind by age 4 years due to tapeto-retinal degeneration, and are bedridden and mute by 5 years, requiring tube feeding. Myoclonic jerks prominent in the face but also involving trunk and extremities set in. Hypotonia is replaced by spasticity with flexion contractures as the disease progresses. Mottled, cold hands and feet are common. Hypothalamic involvement leads to hyperthermia and hypothermia. The former leads to negative fever workups. Excessive secretions and weak breathing effort result in pneumonia. Infections and refractory seizures are the cause of demise during the second decade of life (261,625).

**104.14.4.2 Juvenile Phenotype.** Onset is delayed to ages 6–8 years. Initial progressive cognitive decline is followed by seizures, ataxia and motor dysfunction. Vision loss is variable and survival up to the fourth decade is possible.

**104.14.4.3 Clinical Diagnostic Tests.** CLN2: Tripeptidyl peptidase 1 (TTP1) enzyme activity can be measured in leukocytes, cultured fibroblasts, amniocytes, dried blood spots, and saliva. Fibroblast TTP1 activity is approximately 17,000 micromoles produced per hour per mg of protein. The TTP1 activity in CLN2 disease typically is lower than 5% of normal activity. DNA-based diagnosis is available, but less practical, particularly if the involved mutation or mutations are unknown. Usually, the most commonly reported mutations are ruled out first. Ultrastructural examination of a skin biopsy provides diagnostic information as well. Curvilinear bodies enclosed within unilamellar endosomes in

endothelial cells, pericytes, and Schwann cells are diagnostic. Sometimes, fingerprint profiles also appear. EM remains a valuable diagnostic tool when other diagnostic measures are unavailable, and in unusual or atypical cases. The ERG shows reduced amplitudes early, before thinned vessels and pale discs become apparent. It is extinguished after a few months. Large and characteristic giant occipital polyspike discharges are activated in response to a single flash of light or to low-frequency repetitive stimulation by EEG, and is nothing but the early appearance of an exaggerated VER. VER and somatosensory-evoked response wave amplitudes are high, but these tests are not particularly useful. An initial CT or MRI may be normal, but within 6 months of onset, cerebral and especially infratentorial atrophy are prominent. Children with CLN2 disease, late infantile type, begin to differ from controls at age 5 years where a 40% loss in cerebellar volume and marked dilatation of the ventricular system are observed. Caudate and thalamic volumes are markedly reduced compared to age-matched controls with the relative preservation of brainstem volume early in the course of the disease (262,626).

**104.14.4.4 Pathology.** Brain weight is markedly diminished and is anywhere from 250 to 700 g. The calvarium is thickened. Sulci are wide in the occipital regions and elsewhere. Cerebellar folia are prominent and ventricles are wide. There is laminar necrosis and massive neuronal loss with some preservation of layer III. The preserved neurons represent meganeurites. Purkinje and granule cells are wiped out from the cerebellum. Putamen and subthalamic and brainstem nuclei also demonstrate neuronal loss. The white matter is pale and there is reactive astrocytosis with activation of microglia, yet monocyte-derived macrophages evident in chronic and acute inflammation are conspicuously absent. This strongly implies that the initial event in LINCL is neuronal loss with a secondary, reactive gliosis. The few neurons remaining have swollen cell bodies, and a granular cytoplasm that reacts positively with PAS, Luxol fast blue, and Sudan black B. The white matter appears intact, negating a primary inflammatory component in LINCL. Condensed chromatin by EM, upregulation of Bcl-2 protein, and positive terminal deoxynucleotidyl transferase dUTP Nick End Labeling (TUNEL) stains provide substantiation for apoptosis (627). There is a strong reactivity with an antibody to subunit C of mitochondrial ATP synthase (628). The cause for this remains obscure, but may represent a form of apoptosis common to neurodegenerative disease known as mitophagy. Neurons and other cells contain curvilinear inclusions enclosed within a single membrane, sometimes admixed with fingerprint profiles. This is seen in smooth muscle cells, eccrine sweat glands, endothelial cells, and pericytes outside the brain. A pathological feature that distinguishes CLN2 disease from other vLINCL forms is the invariant presence of curvilinear bodies, which occurs only occasionally in other vLINCL forms. Prenatal diagnosis has been

achieved by analyzing the ultrastructure of amniocytes at 16–17 weeks gestation, measuring enzyme activities and *CLN2* gene sequences.

For clinical staging, the Weill Cornell LINCL scale and the modified Hamburg LINCL scale are used. Both correlate with age and time since the onset of initial clinical manifestations, but the former also utilizes imaging measures (629).

**104.14.4.5 Biochemistry.** Pepstatin-insensitive lysosomal tripeptidyl peptidase is a 46-kDa protein that normally removes tripeptides from the N-terminus of proteins. TPP1 activity is lost in the brain, liver, heart, kidney, and the intestine of LINCL patients. TPP1 expression is developmentally controlled, reaching its peak at the same age of symptom onset in LINCL (630). Loss of TPP1 activity contributes to the accumulation of mitochondrial subunit C in the lysosome. Residual activity of mutated TPP1 can ameliorate the LINCL phenotype (631). It is not known how subunit C accumulation relates to TPP1 deficiency. NCL disorders with normal TPP1 activity (*CLN3*, *CLN4*, *CLN6*, and *CLN8*) also accumulate subunit C. It more than likely represents a secondary process and may be related to the increase in apoptosis observed in *CLN2*-, *CLN3*-, *CLN6*-, and *CLN8*-deficient cells. Measurement of TPP1 enzyme activity is the most practical diagnostic tool available for diagnosis of LINCL.

**104.14.4.6 Genetics.** LINCL is a panethnic, autosomal recessive disorder with cases diagnosed from countries from all continents. It is the second most common form of NCL disease in the United States and accounts for one-third of cases. Over 72 mutations have been described so far. Two common mutations account for 65% of diagnosed cases in the United States. One is a nonsense mutation, Arg208X, and the other affects a splice-junction site, IVS5-1G>C. Some cases with a milder course and later onset bear one of these two mutations on one allele, and an Arg447His on the other. Dog and mouse models for this disease are now available (632,633).

**104.14.4.7 Management and Treatment.** Treatment is supportive. Most problematic are recalcitrant seizures requiring multiple anticonvulsants. Valproic acid, clonazepam, and clorazepate have benefited a number of cases. Phenobarbital, Zonigran, and Keppra are helpful in others. Tube feeding becomes necessary in most cases after 5–7 years of age. Frequent aspiration pneumonias reflect difficulty swallowing. Contractures must be minimized with diligent physical therapy. BMT has failed. Replication deficient AAV gene transfer vector (AAV2-mediated *CLN2* gene transfer) has been studied in mice, rats, and nonhuman primates with *CLN2*. A safety trial for therapy in 10 children with mutations in *CLN2* using delivery by brain surgery is completed without any benefit. Enzyme replacement trials in a mouse model for *CLN2* disease show that it is possible to deliver TPPI enzyme to the brain using the CSF. Stem cell therapy is currently being developed. It has been proposed that use of

the antiapoptotic drug, flupirtine, may slow progression of this disease. The safety of this drug and its analgesic, antispasmodic, and weak anticonvulsant effects make it particularly attractive (288). The efficacy of this drug in LINCL is not determined.

#### **104.14.5 Variant Late Infantile Forms (vLINCL; Finnish Type: *CLN5*-Deficient; Costa Rican/Portuguese/Lake-Cavanaugh Variant: *CLN6*-Deficient; Northern Epilepsy or Epilepsy with Mental Retardation or EPMR, Turkish vLINCL: *CLN8*-Deficient and Turkish vLINCL: *CLN7/MFSD8*)**

A series of variant late infantile types with ages of onset between 5 and 8 years and a clinical profile reminiscent of the late infantile type, but with a protracted course have been described. So far, four different genes are identified. The *CLN5* gene, identified in Finland and believed to be exclusively Finnish, was reported later in patients of various ethnic backgrounds and in cases with early juvenile onset (634,635). Four patients of Serbian and German descent with juvenile NCL, previously described as *CLN9*, are now reclassified to the *CLN5* variant. This has brought new cytological and biochemical data to this *CLN5* variant with emergence of new clues to the function of the *CLN5* protein (580,581). The *CLN8* gene defective in Northern Epilepsy was identified in the northeast of Finland. Some but not all Turkish cases with variant LINCL are due to mutations in the *CLN8* gene. The variant LINCL type, also known as Costa Rican/Portuguese or *CLN6*-deficient type, affects patients with Venezuelan, Pakistani, and Indian descent and from the United States. The first reports were called “early juvenile” and are referred to as the Lake-Cavanaugh variant (293,414,636). In 2007, a novel gene named *MFSD8* was found affected in a subset of Turkish families with variant LINCL (587) and later identified as a common cause of vLINCL in different populations (612,637,638).

##### **104.14.5.1 Clinical Description.**

**104.14.5.1.1 Finnish Variant LINCL (*CLN5*-Deficient).** Late infantile phenotype: Initial symptoms may be clumsiness and/or difficulties concentrating noticed at age 4.5 years. Cognitive decline at the age of 6 and generalized and myoclonic epilepsy at the age of 8 follow. Children are blind by the age of 8, lose the ability to walk by the age of 10, and die between the ages of 14 and 34 years. Mutations in the *CLN5* gene can also cause milder disease.

**104.14.5.1.2 Early Juvenile Phenotype (*CLN5*-Deficient).** The clinical course is similar to JNCL disease with decreased vision at the age of 4 years, cognitive decline at the age of 6 years, and ataxia and rigidity by the age of 9 years. Dysarthria, scanning speech, and mutism may set in by the age of 12 years. Hallucinations and behavior problems are common and intractable seizures may develop during the early teens. Retinitis with pigmentary changes is

documented. Behavior disturbances/mental deterioration can be the dominant manifestations at onset (635).

**104.14.5.1.3 Northern Epilepsy or Epilepsy with Mental Retardation (CLN8-Deficient).** The disease manifests with frequent but short generalized tonic-clonic convulsions and complex partial seizures, as well as cognitive decline to a low average level after the age of 5 and before puberty. After puberty, noted are slow movements and a plateau in the rate of cognitive decline. In the final stage, seizures diminish and mental dullness/decline result in mental retardation by the age of 40 years. At the end, patients are clumsy, ataxic, and have impaired vision. Patients die at the age of 17 years to late middle age.

**104.14.5.1.4 Turkish vLINCL or tLINCL (CLN8-Deficient).** The clinical phenotype is more severe than that of EPMR. Patients present between the ages of 2 and 5 with severe seizures, intellectual decline, and blindness. Behavioral problems develop, and are prominent by the age of 8–9 years. Most patients are wheelchair-bound by 10 years of age.

Costa Rican/Portuguese vLINCL/Lake-Cavanaugh variant (CLN6-Deficient) (639). The onset is between the age of 18 months and 8 years with ataxia and speech difficulties following normal development. Visual failure due to retinitis pigmentosa, myoclonic jerks, and other seizures and intellectual decline follow. Loss of motor skills occurs between 4 and 10 years. Patients succumb to the disease in the early to mid teens. Most mutations in the *CLN6* gene cause a variant of late infantile onset neuronal ceroid lipofuscinosis. Recently, mutations in *CLN6* have shown to be a major cause of recessive Kufs type A disease, an adult form of NCL (see below).

**104.14.5.1.5 Turkish Variant Late Infantile NCL (CLN7/MFSD8-Deficient).** Disease onset/progression is similar to CLN6 disease. Mutations in the *CLN7* gene can cause milder disease. The occurrence of seizures and motor difficulties before visual failure is peculiar to CLN6 and CLN7 diseases.

**104.14.5.2 Clinical Diagnostic Tests.** JNCL with atypical features or symptoms suggestive of classical LINCL, normal PPT1/TPP1 enzyme activities, absence of vacuolated lymphocytes, and a normal *CLN3* gene suggest one of the variant LINCL types. Skin/rectal biopsy ultrastructure, ethnic background, and subtle features for one of these subtypes may raise suspicion in favor of one of the variant LINCL types. Fingerprint and rectilinear structures suggest the CLN5 variant. A combination of curvilinear and fingerprint bodies favors the Costa Rican/Portuguese variant. Finnish CLN8 EM findings include loose curvilinear-like structures, and the Turkish CLN8 variant is characterized by dense fingerprint profiles and dark amorphous material. MRI of CLN6 and CLN5-deficient vLINCL demonstrates severe cerebral and cerebellar cortical atrophy, low densities in the thalami and basal ganglia, and hyperintensities of the white matter. MRI of tLINCL/CLN8 is characterized by cerebellar and cerebral atrophy as well as atrophy of the brainstem. The

EEG shows giant amplitude occipital spikes in response to low-frequency photic stimulation in all the variants. In CLN7 disease, brain MRI demonstrates global atrophy and periventricular leukoencephalopathy. In view of the common clinical and radiological findings in the vLINCL group, molecular genetics methods are the mainstay for diagnosis. In the case of CLN, sequencing of the *MFSD8* gene remains the most practical alternative for diagnostics, as the majority of patients have private family mutations.

#### 104.14.5.3 Pathology.

**104.14.5.3.1 Finnish Variant LINCL (CLN5-Deficient).** The brain weighs about 500g. Severe cerebellar atrophy is documented. Findings are otherwise very similar to classical LINCL. Strong immunoreactivity to subunit C of mitochondrial ATP synthase and weak immunoreactivity to saposins is reported. EM is conspicuous for the presence of rectilinear profiles, curvilinear, and fingerprint bodies (367,368,640). Neuronal loss occurs both in the cerebellum and the neocortex. Cortical neuronal loss affects laminae III and V most severely. In the cerebellum, there is almost the complete loss of Purkinje and granule cells. Data from *Cln5*-deficient mice reveal that neuron loss starts in the cortex and subsequently involves the thalamus, as opposed to CLN2, CLN3 and CLN10, where the loss of thalamic relay neurons occurs before the onset of neuron loss within the corresponding cortical region (641).

**104.14.5.3.2 Costa Rican/Portuguese vLINCL/Lake-Cavanaugh Variant (CLN6-Deficient).** The brain weighs between 600 and 900g. Neuronal loss is pervasive and very prominent in neocortex layer V. Granule cells in the cerebellum are wiped out completely, but a few Purkinje cells remain. There is strong immunoreactivity with subunit C in neuronal tissues, which is absent in peripheral organs. By EM, curvilinear, fingerprint bodies and rectilinear profiles are documented in the brain. Rectilinear, fingerprint, and curvilinear bodies are present in viscera.

**104.14.5.3.3 Northern Epilepsy or Epilepsy with Mental Retardation (CLN8-Deficient).** The brain weight at autopsy is between 1000 and 1600g. The brain may appear normal or mildly atrophic. Storage material and meganeurites are prominent in layer III of cortex. Neuronal loss is conspicuous in cortex layer V, with minimal accumulation of subunit C in substantia nigra, cerebellar Purkinje cells, and locus ceruleus, and strong reactivity with antibodies to  $\alpha$ -amyloid and saposin D. EM of storage bodies is noted for curvilinear and granular material.

**104.14.5.3.4 Turkish vLINCL or tLINCL (CLN8-Deficient).** EM of skin is noted for curvilinear, rectilinear, and fingerprint profiles (640).

**104.14.5.3.5 Turkish Variant Late Infantile NCL (CLN7/MFSD8-Deficient).** The ultrastructural pattern of the storage material in CLN7 patients, consisting of rectilinear/fingerprint complexes occasionally associated with curvilinear inclusions, closely resembles EM findings in other vLINCL forms.

**104.14.5.3 Genetics.**

**104.14.5.3.1 Finnish Variant LINCL (CLN5-Deficient).** The *CLN5* gene localizes to chromosome 13q21.1–q32. There are 27 disease-causing mutations reported pan-ethnically. A 2-bp deletion in exon 4 (c.1175delAT) causes 94% of Finnish cases. Most result in the classical LINCL phenotype. A one base pair insertion in exon 1 (c.291dupC) responsible for early onset (4 months) NCL was reported in Argentina, and late onset (age 17) missense mutations were also reported in exons 2 (c.335G>A, c.377G>A) and 4 (c.1121A>G).

**104.14.5.3.2 Costa Rican/Portuguese vLINCL/Lake-Cavanaugh Variant (CLN6-Deficient, CLN6 disease).** The *CLN6* gene localizes to 15q21–q23. The nonsense mutation reported in 20 Costa Rican families, c.214G>T is the most common. Fifty-three mutations are recognized. This variant has a worldwide prevalence with cases reported from Turkey, Pakistan, Costa Rica, Portugal, Saudi Arabia, and Gypsy families from the Czech Republic. A 2-bp deletion in exon 4 (c.395\_396delCT) is described from India, Italy and Saudi Arabia. The *nclf* mouse is a naturally occurring model for *CLN6*-deficient vLINCL (582).

**104.14.5.3.3 Northern Epilepsy or Epilepsy with Mental Retardation (CLN8-Deficient) and Variant Turkish tLINCL.** The *CLN8* gene localizes to chromosome 8p23.3. A single-point mutation in exon 2 (c.70C>G) accounts for all Northern Epilepsy patients. The 13 other mutations cause the clinically more severe phenotype. These occur in Turkey, Pakistan, Germany, Finland, Italy and Israel. The *mnd* mouse is a naturally occurring animal model for *CLN8*-deficient variants (586).

**104.14.5.3.4 Turkish vLINCL CLN7/MFSD8.** There are 23 disease-causing mutations in the *MFSD8* gene localized on 4q28.2. The most common mutation is a missense mutation affecting exon 10 (c.881C>A), reported from Slovakia, Spain, Italy, and Turkey.

**104.14.5.4 Biochemistry and Cell Biology.** *CLN6* and *CLN8* proteins (*CLN6p*, *CLN8p*) are transmembrane proteins that reside in the ER. Evidence shows that *CLN6p* is required for degradation pathways via lysosomes through an unknown mechanism (642). When screened against a human fetal brain library, *CLN6* peptide fragments interacted with collapsin response mediator protein-2 (CRMP-2), a protein that guides axonal growth (643). This may have implications in the maturation and integrity of axons in vLINCL patients.

*CLN8p* is predominantly localized in the ER but colocalizing experiments showed *CLN8* staining beyond the ER, toward the neuronal periphery (644). Further, mouse experiments corroborated the existence of *CLN8p* outside the ER indicating that *CLN8p* has an unidentified vesicular localization in neurons. *CLN8p* belongs to the TLC (TRAM Lag1 *CLN8*) family of proteins, which includes ceramide Synthase enzymes (CerS1-6), and *CLN8p* functions suggested have included lipid

synthesis, trafficking, and as a sensor (645). Examination of lipid extracts from EPMR patients (646), and *mnd* mice (581) revealed reduced levels of ceramide and its downstream metabolites. Taken together, these results support a role for *CLN8p* in sphingolipid homeostasis through an undetermined mechanism. The *CLN5* protein is a lysosomal glycoprotein. *CLN5*-deficient fibroblasts derived from German and American Serbian patients have a distinctive morphology and biochemical phenotype. They are small, rounded, and adhere poorly to the culture dish. They grow rapidly, but with an increased sensitivity to apoptosis. A number of genes involved in cell adhesion and apoptosis are dysregulated by gene profiling and are posted at ([www.dbsr.duke.edu/pub/cln9/](http://www.dbsr.duke.edu/pub/cln9/)). Gene expression of cyclins A2, B1, C, E2, G1, and T2 were increased, and expression of cyclin D1, a proto-oncogene involved in malignant transformation of breast tissue was decreased, as was member 1A of the tumor necrosis factor superfamily. Subunits of cytochrome c oxidases and glutathione S-transferase were also increased. Levels of sphingolipids downstream of dihydroceramide synthase (CerS) in the de novo sphingolipid synthesis pathway: Ceramide sphingomyelin, lactosylceramide, CTH, and globoside were decreased 60–100%. The key regulating enzyme in the ceramide de novo synthetic pathway, serine palmitoyl transferase, was three- to four-fold upregulated. Recent work showed that in the setting of a defective *CLN5* protein,  $\gamma$ -actin fails to bind to CerS1 on one hand and to vimentin and histone proteins on the other hand (581).  $\gamma$ -Actin is the major cellular intermediate filament and is involved in cellular morphology, division and intracellular movements. Vimentin plays a crucial role in cellular shape, resilience and intracellular transport of globoside. Histones are known to regulate the cell cycle. In view of the function of the above proteins, it is likely that this defective protein interaction brought about by defects in *CLN5p* could explain the *CLN5*-deficient phenotype. Recent work showed molecular connections of *CLN5p* to five other NCL proteins: *CLN1/PPT1*, *CLN2/TPP1*, *CLN3*, *CLN6* and *CLN8* proteins suggesting a central role for *CLN5p* in the NCL network. This implies that these proteins may be functionally related. A close interaction between *CLN5* and *CLN8* proteins is further supported by the fact that *CLN8p* is the only NCL protein to correct the *CLN5*-deficient cellular phenotype in these cells and both *CLN5* and *CLN8* are implicated in ceramide synthesis, particularly impacting the step catalyzed by dihydroceramide synthase. This can have useful implications for therapy. Fenretinide, an activator of CerS, improved the *CLN5* phenotype in vitro. This could also apply to *CLN8*-deficient cells.

**104.14.5.5 Management and Therapy.** Supportive therapies for these variants are very similar to those outlined for classic LINCL and JNCL. Northern Epilepsy responds very well to monotherapy with clonazepam, with some patients remaining seizure free for many years

on this drug. Seizure frequency in this variant tends to decrease over time.

#### 104.14.6 Juvenile Neuronal Ceroid Lipofuscinosis or Juvenile Batten Disease (CLN3 Disease, JNCL, Spielmeyer–Vogt–Batten–Mayou, CLN3-Defective/Deficient)

There is a preponderance of JNCL cases with Northern European ancestry (Finland, Iceland, Norway, Sweden, Denmark, Germany, and Holland), and notable absence of African or Jewish cases. Japanese, Portuguese, Polish British, Turkish, Moroccan, Lebanese cases, and others from many countries have been described. It is the most prevalent type of NCL in the United States (261). The first Batten variant to be recognized was JNCL, and the gene responsible for it, CLN3, was first to be cloned (603). Description of the first juvenile cases is credited to a Danish physician, Otto Christian Stengel, in 1826 (601). The four affected siblings of a Norwegian family established the genetic nature of the illness.

**104.14.6.1 Clinical Description.** Early development is unremarkable and the first symptom is decreased central vision due to retinitis pigmentosa at 4–6 years of age. Patients become completely blind at variable ages from 10 to 14 years. Complete blindness and a disturbed sleep–wake cycle and insomnia are common. Some affected children reported difficult behavior between the ages of 7 and 9 years. By the age of 10 years, cognitive decline is apparent with diagnosis first suspected by teachers for the blind who are familiar with this condition in the pediatric visually impaired population. Seizures appear at the age of 12 years or sooner, but may not declare themselves until the age of 14 years. Early-onset seizures, difficult to control, often foretell a more rapidly declining course. Repetitive echolalic speech is universal to all cases and perseveration of motor actions becomes common. A cogwheel rigidity of the limbs and a stooped, shuffling gait is reminiscent of patients with Parkinson’s disease. Intention tremor may be present and can be of variable severity. Patients stabilize for a few years in their mid teens. Psychiatric symptoms occur in 74% of patients. Many become depressed and agitated, some become aggressive and psychotic. These patients often have a positive family history for unipolar or bipolar illness. Treatment is not always necessary, as it does aggravate extrapyramidal signs and symptoms. Hallucinations are common, but are often of a pleasant and repetitive nature. Some patients have constant imaginary friends. Growth and physical maturity are normal, and sexual development may become a problem, particularly for teenage girls. Contraceptive measures are often sought and given for affected teenage girls. Drooling, difficulty swallowing, and weight loss become problems late in the course, and are managed by gavage feeding. Temperature instability with hypothermia (93F) alternating with

hyperthermia is caused by hypothalamic disease. Seizures increase to 150–200 per day in spite of numerous medications and become impossible to control. Some patients develop a cardiomyopathy or sick sinus syndrome with bradycardia, requiring pacemakers. Patients succumb in their early to mid-twenties due to uncontrollable seizures or cardiopulmonary arrest. A small number of patients survive into the fourth decade.

**104.14.6.2 Clinical Diagnostic Tests.** DNA-based CLN3 gene tests confirm the diagnosis. EEG is abnormal from the age of 9 years onwards with large amplitude spike and slow wave complexes. CT and MRI, though initially normal, ultimately reveal cerebral atrophy with gaping sulci and large ventricles (Figure 104-12). Cerebellar atrophy is prominent usually after the age of 15. Morphometric MRI measurements document loss of hemisphere, caudate, thalamic, and lenticular volumes (262). A voxel-based morphometric study (647) showed marked reduction in the gray matter volume of the dorsomedial thalami and decreased white matter volume of the corona radiata. A low signal is observed in the white matter in T2-weighted images. PET shows decreased glucose utilization in the calcarine area, which progresses to involve all gray structures. The latter two techniques are not routinely offered, but were carried out to better understand disease progression. ERG is abnormal before decreased vision becomes apparent. Visual-evoked potentials show reduced amplitude potentials, and somatosensory-evoked potentials are enhanced. EM of a skin biopsy is often helpful, particularly if the mutations are not known. Schwann cells, endothelial cells, pericytes, neurons, macrophages, and eccrine sweat glands contain typical inclusions. Fingerprint-like inclusions enclosed by a unit membrane are common, often in association with curvilinear inclusions. Vacuolated lymphocytes are a hallmark of JNCL, but blood must be processed swiftly and correctly; otherwise false positives become problematic. Few diagnostic laboratories can evaluate this. Skin EM is more robust and reliable. On neuropsychological testing, children with CLN3 disease had significant impairment in auditory attention, memory, verbal intellectual function, and fluency. Neuropsychological impairment was progressive over time and correlated with disease duration and motor function (648).

**104.14.6.3 Pathology.** The brain at death weighs between 450g and 1100g. There is thinning of the cortical mantle with moderate neuronal loss, gliosis, and accumulation of autofluorescent material that is Sudan Black B and PAS positive. There is selective necrosis of stellate cells in cortical layers II and III and the loss of pyramidal cells in layer V. Meganeurites are seen in the basolateral amygdaloid complex and in cortical layer V. Purkinje cell and granule cell loss is dramatic. Apoptotic neurons with dark, shrunken, and fragmented chromatin are seen in the cerebral cortex by EM. A number of neurons are TUNEL-stain positive, confirming the

existence of apoptotic neurons. Surviving neurons are immunoreactive with antibodies to Bcl-2, a neuroprotective protein, and subunit C. Lipopigment accumulates in anterior horn cells of the spinal cord and receptor cells of the organ of Corti. In neuronal cells, fingerprint profiles and in non-neuronal cells curvilinear inclusions prevail. Also, blood lymphocytes contain cytoplasmic vacuoles.

**104.14.6.4 Biochemistry, Cell Biology, and Pathophysiology.** Despite a decade of research into the function of CLN3 protein, the role of this protein remains elusive. CLN3 has been reported to be present in multiple cellular compartments including nucleus, Golgi, mitochondria, PM, LRs, endosomes and lysosomes, suggesting that this protein dynamically traffics between cellular compartments and may function in multiple regions of the cell. The motif consisting of the amino acids valine, tyrosine, phenylalanine, alanine, and glutamic acid or VYFAE, embedded within the CLN3 protein is part of a larger galactosylceramide lipid, raft-binding domain. In CLN3-deficient cells, both mutant CLN3 protein and galactosylceramide (GalCer) remain in the Golgi, never reaching their final destination or LRs. This is reversed after restoring CLN3 to deficient cells suggesting that CLN3 may function as a GalCer transporter from Golgi to LRs. The increase in apoptosis is initiated from LRs, and the revved up production of sphingolipids is an attempt to correct the GalCer deficiency in LRs. Ceramide, the proapoptotic lipid second messenger, was elevated in JNCL brains (649). This correlated with the identification of apoptosis in JNCL brain and antiapoptotic amino acid stretches within the CLN3 protein (142). In addition, other GSLs and sphingomyelin were elevated, pointing to sphingolipid overproduction (650). The CLN3 protein was upregulated in human and mouse cancer cell lines, and solid colon cancer specimens (651). In the setting of a deficient CLN3 protein, cathepsin D transport and processing are altered. CLN3 was also reported to interact with many proteins including the cytoskeletal protein  $\beta$ -fodrin, the  $\text{Na}^+$ - $\text{K}^+$  ATPase complex (652), and with the Notch and JNK signaling pathways (653). Together, these results imply a role for CLN3 protein in cytoskeleton dynamics, cell migration, and adhesion, and the modulation of ionic flux and lysosomal homeostasis.

**104.14.6.5 Genetics.** The CLN3 gene localizes to chromosome 16p12.1. JNCL is the most common form of NCL in the United States. The prevalence of this autosomal recessive disease is 7 per 100,000 live births in Iceland, and 0.71 per 100,000 live births in Germany. The prevalence drops the further away one is from Scandinavian countries. The prevalence in the United States is less. This classifies JNCL as an orphan disease, according to FDA guidelines. The gene has 15 exons, and the protein is 438 amino acids long and is a hydrophobic protein with 5–7 potential transmembrane domains. It is highly conserved across species. There are over 50 disease-causing mutations. A 1.02-kb deletion accounts for 85% of cases while the remaining

15% result from point or frameshift mutations. DNA-based carrier testing is available, provided the family mutation is known. Prenatal diagnosis has been achieved using EM-based and DNA diagnostics at 11 weeks gestation. It is best to confirm diagnosis at birth in cord blood.

**104.14.6.6 Management and Treatment.** Clearly, JNCL is the most difficult of the clinical types to manage. Initial seizure control is easily achieved with one drug, but late in the course, patients progress to having over 100 seizures per day, in spite of numerous antiepileptic medications. The emotional and psychiatric aspects of JNCL pose neurologists with a therapeutic conundrum. Antipsychotics and mood stabilizers are necessary but they lower seizure threshold and aggravate Parkinsonian symptoms. Insomnia must be addressed with benzodiazepines and other drugs. Weight loss in the final years necessitates gastrostomy tubes for adequate caloric/liquid and medication intake. Anecdotal reports of the antiapoptotic medication, flupirtine, suggest improved seizure control and sleep patterns. Some patients develop bradycardia, requiring pacemaker placement. Death in the early mid-twenties is common. Some patients die early at 13 years of age, and some survive to the age of 40 years. The average survival has increased with the use of feeding tubes and better anticonvulsants and antibiotics. Patients do not suffer and continue to enjoy human contact and music late into the course. CLN3p is a membrane protein and, therefore, protein and/or gene replacement are not actively sought. The immune system seems to be affected in JNCL, albeit in a secondary manner. Immunodeficient and mycophenolate-treated JNCL mice have a milder clinical phenotype than immunocompetent JNCL mice. A clinical trial using mycophenolate in JNCL patients is planned. Prednisolone given to juvenile patients in Finland reduces antibodies to GAD65 without any effect on disease course. Stem cell approaches may some day have a role in therapy. Recently, EGIS-8332, a drug which targets  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor or AMPA receptors, improved the performance of a JNCL mouse model. Trials in mice on talampanel (LY300164), which targets the same receptors used to treat seizures and Parkinson disease, are underway. The hope for lessening the impact of JNCL must await better understanding of the cell biology and biochemistry of this disorder.

## 104.15 Kufs Disease or Adult NCL

### 104.15.1 Clinical Description

Kufs disease represents 1.3% of the NCL. Symptoms start at the age of 30 years, but can present at an earlier age. Both autosomal recessive and dominant inheritance patterns have been described. Type A is the predominant form and is characterized by progressive myoclonic epilepsy followed years later by dementia and ataxia.

Pyramidal and extrapyramidal symptoms occur as well. Mutations in the *CLN6* gene were found to be responsible for a number of cases of Kufs type A disease. In type B, onset may be delayed to after the age of 50 years. Behavioral abnormality and dementia occur early and are closely followed by progressive motor dysfunction, ataxia, and extrapyramidal and suprabulbar symptoms. Facial dyskinesias are common. More recently, mutations in cathepsin F have accounted for some of the Kufs, type B patients described (261). In both, there is absence of retinal pathology and no visual impairment, although marked photosensitivity is observed in some patients with the type A clinical phenotype.

### 104.15.2 Clinical Diagnostic Approach

A skin biopsy is the least invasive diagnostic approach. The presence of mixed (membrane-bound GRODS, rectilinear, and curvilinear) profiles in association with fingerprint-bearing cytosomes without membrane-bound vacuoles is diagnostic. In rare instances, enzyme testing on leukocytes or fibroblasts shows lysosomal PPT1 activity and gene analysis reveals *CLN1* mutations (654). EEG findings may assist in the diagnosis of Kufs disease. In type A, there are generalized atypical spike and slow wave complexes and photoparoxysmal responses at low flash frequencies. In type B, there is generalized slowing (655).

### 104.15.3 Pathology

Brain weight is 900–1245 g. Most dominant ANCL cases show mild to severe global cerebral and cerebellar atrophy with marked depigmentation of the substantia nigra (656–658). Neuronal loss is variable. The stellate cells of cortical layers II and III are severely affected with mild neuronal loss in layer Vb. Purkinje cells of the cerebellum are also considerably reduced in number.

### 104.15.4 Genetics

The genetic defects underlying most cases of ANCL are unknown. Exceptions are those that carry mutations in *NCL* genes with delayed onset (late teenage years or adulthood). These include *CLN1*, *CLN5*, and notably *CLN6* gene defects with cases reported in the United States, Australia, Italy, and Ireland suggesting that *CLN6* mutations are largely responsible for adult NCL (583). In addition, single mutations of chloride channel 6, the *CLCN6* gene, are described in two late-onset NCL patients. More recently, mutations in cathepsin F or *CLN13* have accounted for Kufs disease, type B cases.

### 104.15.5 Management and Treatment

Supportive and palliative measures are the mainstay of treatment.

## 104.16 CONGENITAL NCL/CNCL-CLN10/CATHEPSIN D OR CTSD DEFICIENCY

### 104.16.1 Clinical Description

CNCL is a rare congenital disorder that was first described in 1941 (659). It represents the earliest onset and the most aggressive form of NCL. Clinical features include congenital microcephalus, overriding sutures, receding forehead, and low-set ears. Deceleration of head growth begins prenatally during the third trimester and jerky fetal movements may be interpreted as seizures. Spasticity is congenital and status epilepticus and respiratory insufficiency occur soon after birth. Death occurs within few hours, days, or weeks after birth. A more protracted form of the disease with a course resembling vLINCL has been described (660).

### 104.16.2 Clinical Diagnostic Test

CLN10 disease should be suspected when an infant presents with intractable seizures and microcephaly. Survival is limited to a few days. The later onset, protracted form initially presents with visual disturbances and ataxia. The presence of granular storage material in skin Schwann cells is indicative of CLN10/CTSD deficiency, provided *CLN1*/PPT1 mutations have been ruled out. Diagnosis is confirmed by the measurement of cathepsin D activity or DNA analysis of CTSD.

### 104.16.3 Pathology

The storage material in CNCL stains positively for sphingolipid activator proteins also found in INCL patients.

Postmortem examination reveals extreme brain atrophy with disorganization of neurons in cerebral cortex, and loss of Purkinje and inner granule cells in cerebellum. The white matter lacks myelin (661–664). Most cells within the CNS are loaded with GRODs. Cathepsin D staining is absent in paraffin-embedded brain specimens.

### 104.16.4 Biochemistry, Cell Biology and Pathophysiology

Mature cathepsin D is a ubiquitously expressed, lysosomal protease belonging to the pepsin family (665). It consists of two polypeptides encoded by the *CTSD* gene. Both polypeptides contain an aspartic acid residue essential for enzymatic activity of the mature protein (666,667). The mature protease is 31 kDa in size. There are several proteins described to function as substrates of CTSD in vitro but the in vivo substrates are still unknown. Aspartyl proteinases consist of two domains, each of which contains an aspartate residue. The residues come together and link to a water molecule at the active site where the substrate peptide bond is hydrolyzed.

Hence, mutation of the aspartate residues that may be present at distant regions of the protein results in the elimination of enzymatic activity of cathepsin D, without affecting its processing (668,669).

### 104.16.5 Genetics

The *CTSD* gene consists of nine exons and is located on chromosome 11p15.5. There are a total of four disease-causing mutations in humans. P.Tyr255X results in truncation of the CTSD protein by 158 amino acids causing complete lack of enzymatic activity and CNCL. Other missense mutations result in effects ranging from complete enzyme inactivation to residual enzymatic activity, suggesting that partial enzyme inactivation leads to later onset CTSD. CTSD knockout mice exhibit the earliest onset and most severe phenotype, while American bulldogs carrying a missense mutation (p.Met199Ile) with 36% residual CTSD activity, start developing symptoms relatively late (between 1 and 3.5 years).

### 104.16.6 Management and Treatment

Currently, only symptomatic treatment is available especially in patients with later onset CTSD deficiency where the main purpose is to ameliorate motor and behavioral complications as well as feeding difficulties.

## ACKNOWLEDGMENT

The authors thank Ms Hala Maakaron for her expert assistance in preparing this manuscript.

### Biographies

**Dr Boustany** completed her Medical degree and Pediatric training at the American University of Beirut in 1980. She subsequently specialized in Pediatric Neurology at the Massachusetts General Hospital (MGH), Harvard Medical School, followed by postdoctoral training in Neurogenetics/Neurochemistry. In 1985, she joined the Neurology faculty at MGH, and stayed for four and a half years. During that time, she was the Co-Director of the Lysosomal Storage Disease Laboratory at the Shriver Center for Mental Retardation. She moved to Duke University in 1989, where she was on the faculty in Pediatrics and Medicine and completed a fellowship in Molecular Biology at the University of North Carolina at Chapel Hill. She became full Professor in Pediatrics and Neurobiology in 2003. She established her research laboratory at Duke in 1992, which remained operational until December, 2007. In 2006, she moved to head the Abuhaidar Neuroscience Institute at the American University of Beirut, a position she held until July 2009. She currently directs the Neurogenetics Program and heads the Division of Pediatric Neurology at the American University of Beirut Medical Center, where she directs basic research and academic clinical programs. Her research interests are Batten disease, lysosomal storage diseases, sphingolipids and their role in cell death.

**Dr Ibraheem Al-Sharreef** completed training in Pediatrics at the American University of Beirut and has just finished his training in Pediatric Neurology at the same institution.

**Dr Sariah El-Haddad** went to Medical School at the American University of Beirut after which she spent three years in the laboratory of Rose-Mary Boustany as a post-doctoral researcher working on the molecular biology and biochemistry of various forms of the neuronal ceroid lipofuscinoses. She is presently in her second year of Psychiatry training in the Department of Psychiatry at the University of Virginia Health Systems.

**ABBREVIATIONS**

ACALD – adolescent cerebral ALD  
 ACOX – acyl-CoA oxidase  
 ADHAPS – alkyl-DHAP synthase  
 AGT – alanine glyoxylate aminotransferase  
 AMACR – 2-methyl-acyl-CoA racemase  
 AMN – adrenomyeloneuropathy  
 BAAT – bile acid-CoA: amino acid N-acyltransferase  
 CCALD – childhood cerebral ALD  
 CDCA – chenodeoxycholic acid  
 CG – complementation group  
 CNS – central nervous system  
 DBP – D-bifunctional protein  
 DHAPAT – dihydroxyacetonephosphate-acyltransferase  
 DLP1 – dynamin-like-protein-1  
 ER – endoplasmic reticulum  
 ESRD – end-stage renal disease  
 FA – fatty acid  
 HCT – allogeneic hematopoietic stem cell transplantation  
 HSC – human stem cell  
 IRD – infantile Refsum disease  
 LBP – L-Bifunctional protein  
 MFE – multifunctional enzyme  
 MFP – multifunctional protein  
 NALD – neonatal adrenoleukodystrophy  
 PBD – peroxisome biogenesis disorder  
 PBE – peroxisomal bifunctional enzyme  
 PD – peroxisomal disorder  
 PH – primary hyperoxaluria  
 PLP – pyridoxal-5<sup>1</sup>-phosphate  
 PMP – peroxisomal membrane protein  
 PTS – peroxisomal targeting signal  
 RCDP – rhizomelic chondrodysplasia punctata  
 RD – Refsum disease  
 RP – retinitis pigmentosa  
 SKL – serine-lysine-leucine  
 SCP X – peroxisomal sterol-carrier protein X  
 UDCA – ursodeoxycholic acid

VLCFA – very long-chain FA  
 X-ALD – X-linked adrenoleukodystrophy  
 ZS – Zellweger syndrome  
 ZSD – Zellweger spectrum disorder

**105.1 INTRODUCTION**

The peroxisomal disorders (PDs) constitute a diverse group of inherited diseases in man, either caused by (1) the deficient activity of a specific peroxisomal enzyme or metabolite transporter or (2) the functional loss of a specific component of the peroxisome biogenesis system. At present >15 different peroxisomal disorders have been identified all of which are autosomal recessive with the exception of X-linked adrenoleukodystrophy. The prototype of the group of PDs is the cerebro-hepato-renal syndrome, better known as Zellweger syndrome (ZS), as first described by Bowen et al. (1) who described a familial syndrome of multiple congenital defects in two pairs of siblings. This report was soon followed by a series of papers describing additional cases. In 1973, Goldfischer and coworkers (2) published their—in retrospect—seminal findings documenting the absence of morphologically distinguishable peroxisomes in hepatocytes and kidney cortex cells of ZS patients. Until then virtually nothing was known about peroxisomes and this observation was left unnoticed. In fact, much more attention was paid to the mitochondrial abnormalities described in the same paper as is clear from the title “Peroxisomal and mitochondrial defects in the cerebro-hepato-renal syndrome.” Indeed, Goldfischer et al. (2) documented clear mitochondrial abnormalities characterized by a markedly reduced rate of oxygen uptake of mitochondria isolated from a brain biopsy of a ZS patient and a liver biopsy from another

ZS patient with malate (plus glutamate) as substrate but not with ascorbate plus TMPD as substrate. These findings led the authors to conclude that “the cytochrome portion of the electron transport chain is intact but that there is a defect in electron transport prior to the cytochromes” (2). Based on these results ZS was considered to be a mitochondrial disorder. Subsequent studies by other investigators, however, revealed that the mitochondrial abnormalities at the level of the respiratory chain were remarkably variable among patients ranging from near normal to grossly impaired, which already argued against ZS as a mitochondrial disorder. Another argument against ZS as a mitochondrial disorder was the observation that ZS patients usually have no lactic acidemia.

Two key observations in the early 1980s clearly established that ZS is indeed a PD and not a mitochondrial disorder. The first was the finding by Brown et al. reported in 1982 (3) that the plasma levels of very long-chain fatty acids (VLCFAs) in ZS patients were markedly elevated in contrast to the levels of the long-chain fatty acids which were normal. A few years earlier Lazarow and DeDuve (4) had described the presence of a fatty acid (FA) beta-oxidation system in peroxisomes. The significance of such a second beta-oxidation system next to that in mitochondria, had remained unclear, but the findings by Brown et al. (3) immediately suggested that the peroxisomal and mitochondrial beta-oxidation systems might serve different physiological purposes, catalyzing the oxidation of different sets of substrates. This view turned out to be correct as outlined below.

The second key observation was published 1 year later in 1983 by Heymans et al. (5) who reported the marked deficiency of plasmalogens—a specific type of phospholipids—in tissues from ZS patients. Taken together, these observations clearly identified ZS as a disorder of the peroxisome. In subsequent years a number of additional abnormalities has been reported in ZS patients including the accumulation of phytanic acid and pristanic acid, the deficiency of polyunsaturated FAs and the increased urinary excretion of oxalate and glycolate, all of which can be explained on the basis of the metabolic functions of peroxisomes as we know them now. Earlier work had already led to the identification of other abnormalities in ZS patients including the accumulation of pipelicolic acid and the bile acid intermediates di- and trihydroxycholestanoic acid, which were originally thought to result from the mitochondrial abnormalities in ZS patients. Thorough reinvestigation of these abnormalities revealed that they were due to the peroxisomal rather than mitochondrial abnormalities in ZS patients. These detailed studies on ZS have been extremely important since they have led to the development of a set of peroxisomal biomarkers, i.e. metabolites, which can be measured in a single blood specimen. With

this “peroxisomal biomarker panel” at hand, many diseases in which a peroxisomal dysfunction was suspected on clinical grounds could be investigated which has brought us to where we are now: a group of inherited PDs now made up of >15 different diseases (Table 105-1). This peroxisomal biomarker panel continues to be of great relevance up until now and has contributed to the identification of patients with unique aberrant phenotypes hitherto not considered to have a peroxisomal origin (6,7).

## 105.2 PHYSIOLOGICAL ROLE OF PEROXISOMES

In contrast to mitochondria, which contain >1000 different proteins either encoded by the nuclear or mitochondrial genome, peroxisomes are relatively simple organelles containing far less proteins (current estimate: 50–100 different proteins) (8) all encoded by the nuclear genome. One reason for this apparent simplicity is that peroxisomes lack a respiratory chain (note that complex I of the respiratory chain alone already has >50 different protein components) and that the transport properties of peroxisomes are also relatively simple with most low molecular weight substrates and products (i.e. metabolites) going in and out of peroxisomes, not via specific carriers as in mitochondria, but via one or more porins. In this respect, the peroxisomal membrane resembles that of the mitochondrial outer membrane much more than the mitochondrial inner membrane.

Below we will briefly describe the metabolic pathways catalyzed by peroxisomes and the enzymes involved as far as relevant for human diseases.

### 105.2.1 Peroxisomal FA Beta-Oxidation

The peroxisomal FA beta-oxidation pathway resembles mitochondria in many respects and catalyzes the step-wise shortening of FAs by chopping off an acetyl-CoA unit upon each cycle of beta-oxidation. Each cycle involves four subsequent enzyme reactions, which are all required for the removal of an acetyl-CoA unit from a particular FA. The enzyme proteins catalyzing these four reactions are different from their mitochondrial counterparts although there is marked sequence homology between the mitochondrial and peroxisomal beta-oxidation enzyme proteins. Needless to say that different genes encode them.

From a physiological point of view, the most conspicuous difference between the mitochondrial and peroxisomal beta-oxidation systems is the fact that they oxidize different fatty acids. Indeed, the mitochondrial system catalyzes the oxidation of the bulk of FAs derived from our daily diet and converts the acetyl-CoA units as produced upon beta-oxidation into CO<sub>2</sub> and H<sub>2</sub>O via the citric acid cycle to produce ATP. At least in the liver and

TABLE 105-1 The Peroxisomal Disorders

kidneys, the acetyl-CoA units may also be converted into the ketone bodies acetoacetate and 3-hydroxybutyrate, which can be used as source of energy in most other tissues.

Peroxisomes contribute little to the oxidation of FAs derived from our daily diet, which renders peroxisomal beta-oxidation unimportant for energy purposes. However, peroxisomes are important for the oxidation of a range of FAs that cannot be oxidized in mitochondria as described in detail below:

It should be noted that peroxisomes are unable to degrade the acetyl-CoA units to completion, i.e. to  $CO_2$  and  $H_2O$ , or convert them into ketone bodies. Instead, the acetyl-CoA units produced in peroxisomes are transported out of the peroxisome into the cytosol, either as acetylcarnitine or acetic acid followed by subsequent metabolism in mitochondria (9). The different physiological roles of the mitochondrial and peroxisomal beta-oxidation systems are also reflected in different clinical phenotypes associated with deficiencies in either of the two systems.

The FAs that are oxidized in peroxisomes include:

- **Very long-chain FAs** like C24:0 and C26:0 are in part derived from our daily diet but are predominantly synthesized endogenously from shorter-chain fatty acids via chain elongation. Current knowledge holds that VLCFAs are not fully degraded into acetyl-CoA units in peroxisomes but instead are only partially degraded to produce acetyl-CoA units plus medium-chain acyl-CoAs which are then exported to the mitochondria as carnitine esters or as free acids (9) (Figure 105-1A).
- **Pristanic acid** (2,6,10,14-tetramethylpentadecanoic acid) is a branched-chain FA which is not biosynthesized endogenously but is solely derived from dietary sources either directly as pristanic acid itself or indirectly from alpha-oxidation of phytanic acid (Figure 105-1B). Phytanic acid is also derived from dietary sources only. Pristanic acid is known to undergo three cycles of beta-oxidation in peroxisomes with acetyl-CoA, propionyl-CoA and 4,8-dimethylnonanoyl-CoA as end products, which are all transported out of the peroxisomes either as carnitine ester or as free acid (9).
- **Di- and trihydroxycholestanoic acid** (DHCA and THCA) are intermediates in the biosynthesis of the primary bile acids chenodeoxycholic acid and cholic

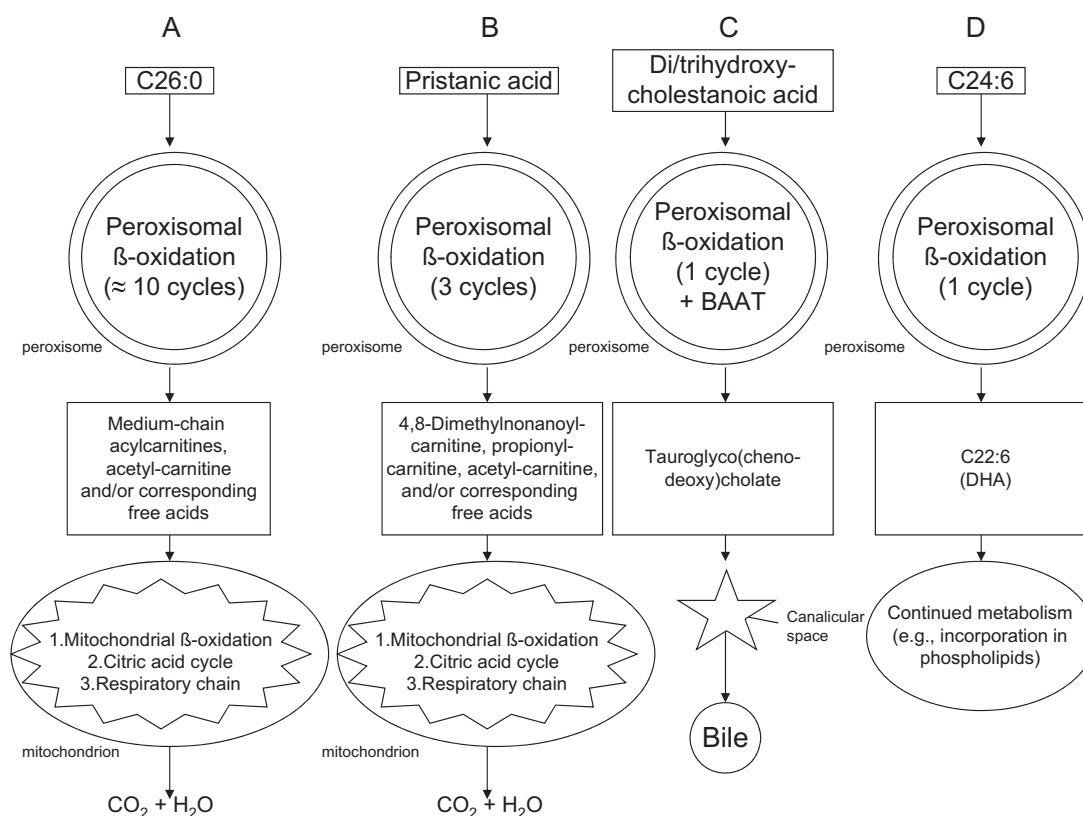

acid respectively and are produced from cholesterol in the liver (Figure 105-1C). After formation of the coenzyme A esters of DHCA and THCA, one cycle of beta-oxidation in peroxisomes produces propionyl-CoA plus the CoA esters of chenodeoxycholic acid and cholic acid which are then converted into the corresponding glycine/taurine conjugates in peroxisomes (9).

- **Tetracosahexaenoic acid** is synthesized from linolenic acid (C18:3n-3) via subsequent steps of elongation and desaturation to produce tetracosanoic acid (C24:3n-3) which undergoes one cycle of beta-oxidation in peroxisomes to yield docosahexaenoic acid (C22:6n-3) (Figure 105-1D).

### 105.2.2 The Peroxisomal FA Beta-Oxidation Enzymes

Peroxisomes contain the full enzymatic machinery to oxidize different FA substrates listed above. These enzymes include:

- **Acyl-CoA oxidases:** Human peroxisomes contain two acyl-CoA oxidases catalyzing the first step of beta-oxidation. The first enzyme (ACOX1) is specific for saturated acyl-CoAs and is nonreactive with 2-methyl-branched-chain acyl-CoA like pristanoyl-CoA

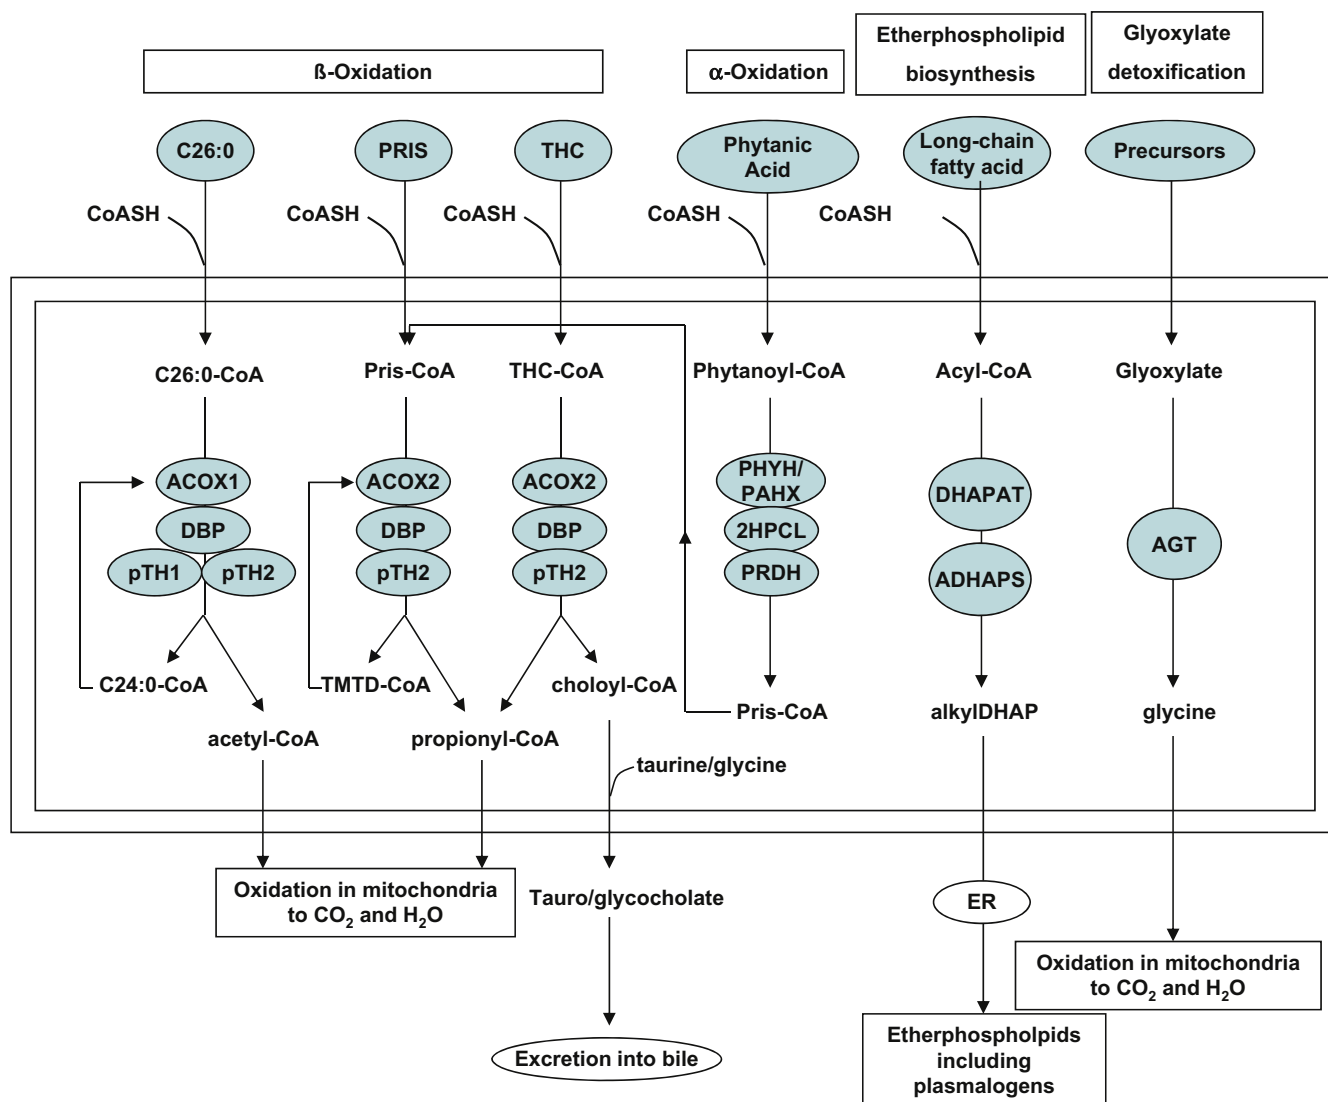

**FIGURE 105-1** Schematic diagram depicting the fate of the main FA substrates oxidized in peroxisomes, which include (1) the VLCFA C26:0 (hexacosanoic acid); (2) the branched-chain fatty acid pristanic acid (2,6,10,14-tetramethylpentadecanoic acid); (3) the bile acid synthesis intermediates DHCA and THCA, and (4) the polyunsaturated fatty acid tetracosahexaenoic acid (C24:6n-3). See text for further details.

and di- and trihydroxycholestanoyl-CoA while the second enzyme (ACOX2) preferentially reacts with pristanoyl-CoA and di- and trihydroxycholestanoyl-CoA. ACOX1 is the dominant enzyme in the oxidation of very long-chain FAs, whereas ACOX2 is indispensable for the oxidation of pristanic acid and di- and trihydroxycholestanic acid. Only human ACOX1 deficiency has been described so far as described in detail below.

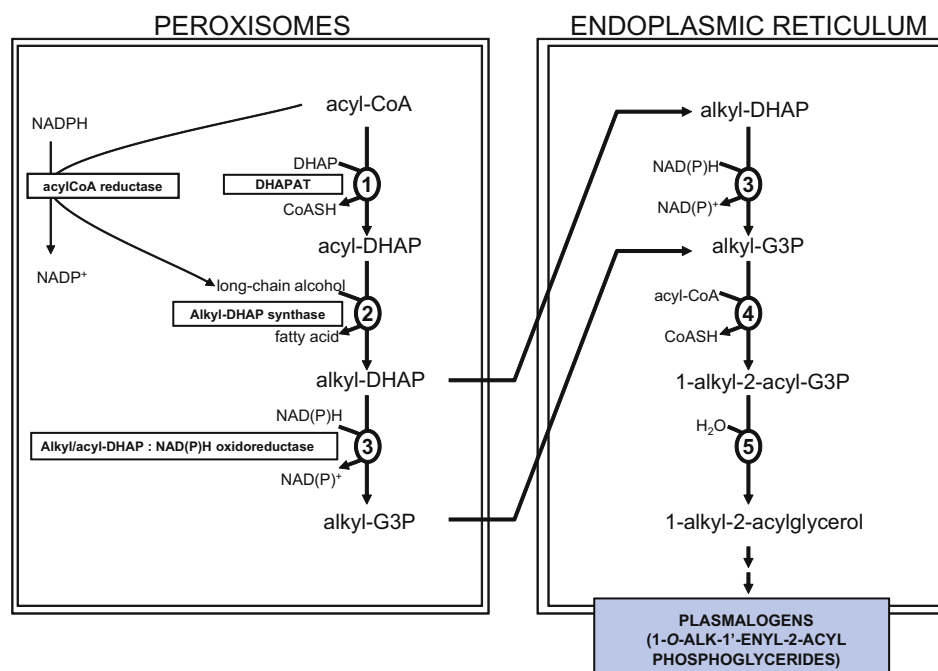

- **Combined enoyl-CoA hydratases/3-hydroxyacyl-CoA dehydrogenase enzymes:** Human peroxisomes contain two different the so-called bifunctional proteins which harbor both enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase activities that allow these proteins to catalyze the second and third step of beta-oxidation in peroxisomes. The enzymes are alternatively named as multifunctional enzyme (MFE) I/II, multifunctional protein (MFP)

1/2, peroxisomal bifunctional enzyme 1/2 and L- and D-bifunctional protein (LBP/DBP), respectively. DBP is the central enzyme involved in the oxidation of virtually all beta-oxidation substrates including C26:0, pristanic acid and di- and trihydroxycholestanic acid (Figure 105-2). The role of LBP in FA oxidation has remained obscure although oxidation of some long-chain dicarboxylic acids appears to involve LBP rather than DBP. Only DBP deficiency has been described in humans as described in detail below.

- **Peroxisomal thiolases:** Human peroxisomes contain two different thiolases named peroxisomal thiolase 1 and 2. The latter thiolase named pTH2, better known as SCPx, is reactive with the 3-oxoacyl-CoA esters of branched as well as unbranched FAs whereas the first thiolase (pTH1) only reacts with the 3-oxoacyl-CoA esters of straight-chain FAs. Only a deficiency of the second thiolase has been described so far (10).

**FIGURE 105-2** Schematic diagram showing the four major metabolic functions of peroxisomes that include: (1) fatty acid beta-oxidation; (2) fatty acid alpha-oxidation; (3) etherphospholipid biosynthesis, and (4) glyoxylate detoxification plus the individual peroxisomal enzymes involved and the end products of each of the four pathways in peroxisomes. See text for further details.

**FIGURE 105-3** Enzymology of the etherphospholipid biosynthesis pathway. Etherphospholipid biosynthesis is fully dependent on peroxisomes since the first two enzymes of the pathway, i.e. DHAPAT and ADAPS are strictly peroxisomal whereas the next enzyme in the pathway is shared between peroxisomes and the ER. All subsequent enzymes are localized in the ER.

In addition to the enzymes described above, peroxisomes contain a number of additional enzymes involved in peroxisomal beta-oxidation. These include: (1) two different acyltransferases including carnitine acetyltransferase and carnitine octanoyltransferase for the conversion of the products of peroxisomal beta-oxidation i.e. acetyl-CoA, propionyl-CoA, and other chain-shortened acyl-CoAs into the corresponding carnitine esters, (2) different thioesterases catalyzing the cleavage of acyl-CoA esters into the corresponding free acids plus coenzyme A, (3) an enoyl-CoA isomerase and dienoyl-CoA reductase enzyme, and (4) the enzyme 2-methylacyl-CoA racemase. The latter enzyme abbreviated as AMACR, is required for the conversion of the (2R)-methyl group—as present in for instance pristanic acid—into the (2S)-configuration (Figure 105-4). The AMACR enzyme plays an indispensable role in the oxidation of (2R)-methyl-branched-chain FAs like pristanic acid, as well as di- and trihydroxycholestanic acid simply because the branched-chain acyl-CoA oxidase (ACOX2) only reacts with (2S)-acyl-CoA esters. Racemase deficiency has been identified in humans as described below (11).

### 105.2.3 Etherphospholipid Biosynthesis

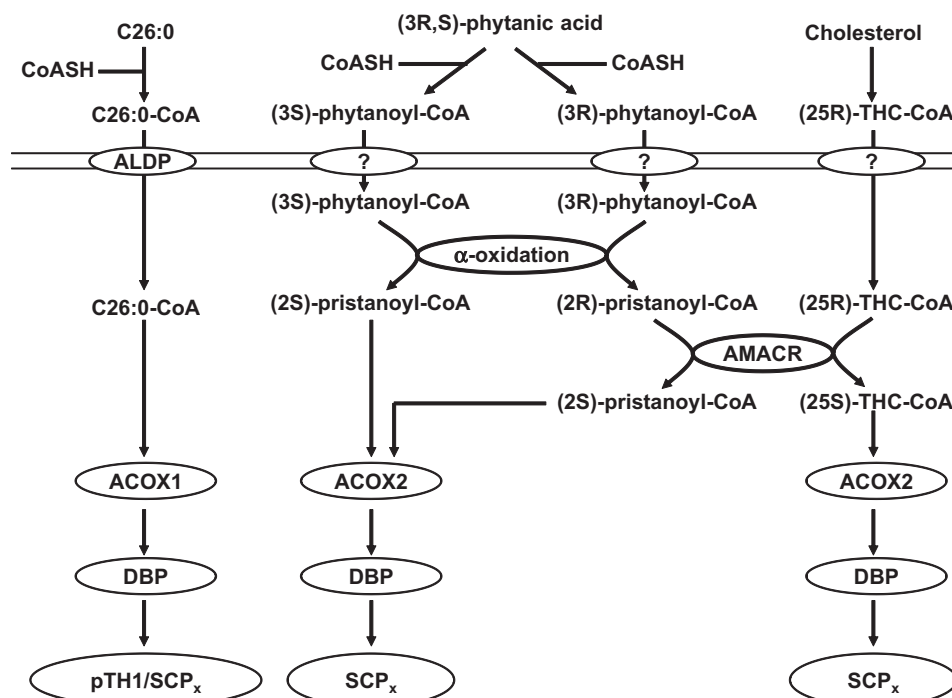

Etherphospholipids are a special class of phospholipids, which differ from the regular diacylphospholipids in the sense that an ether-linkage rather than an ester-linkage is present at the *sn*-1 position of the glycerol backbone. The ether group at *sn*-1 can have two different configurations, which explains why two groups of etherphospholipids can be distinguished either with a

1-O-alkyl or 1-O-alk-1'-enyl linkage. The latter phospholipids (1-O-alk-1'-enyl-2-acyl-phosphoglycerides) with an alpha-, beta-unsaturated ether-bond are also known as plasmalogens. Platelet-activating factor (1-O-alkyl-2-acetyl-glycerophosphocholine) is the best-known etherphospholipid. Figure 105-3 depicts the enzymology of the etherphospholipid biosynthetic pathway with part of the enzymes localized in peroxisomes and another part in the endoplasmic reticulum. Biosynthesis of etherphospholipids starts in the peroxisome with production of acyl-DHAP as catalyzed by the peroxisomal enzyme dihydroxyacetonephosphate-acyltransferase (DHAPAT), followed by the introduction of the typical ether-bond by the enzyme alkyl-DHAP synthase (ADHAPS). Both enzymes are strictly peroxisomal. The third step is catalyzed by the enzyme alkyl/acyl-DHAP: NAD(P)H oxidoreductase, which has a bimodal distribution in both peroxisomes and endoplasmic reticulum (Figure 105-3). The product alkylglycerol-3-phosphate (alkyl-G-3P) undergoes subsequent conversion into plasmalogens. Genetic deficiencies at the level of DHAPAT and alkyl-DHAP synthase have been described in literature as described below. Both of these deficiencies give rise to rhizomelic chondrodysplasia punctata (RCDP).

### 105.2.4 FA Alpha-Oxidation

3-Methyl-branched FAs cannot be beta-oxidized directly due to the presence of a methyl group at 3-position. Instead, 3-methyl FAs first undergo alpha-oxidation, which allows removal of the terminal

**FIGURE 105-4** Detailed description of the peroxisomal alpha- and beta-oxidation systems showing (1) the close interaction between the two pathways with respect to the oxidation of the branched-chain fatty acid phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) and (2) the importance of the enzyme AMACR in the oxidation of phytanic acid, pristanic acid and the bile acid synthesis intermediate THCA. See text for further details.

carboxyl group as  $\text{CO}_2$ . One of the most important 3-methyl-branched FAs is phytanic acid, long known to accumulate in Refsum disease (RD) as well as in other PDs as discussed below. The mechanism involved in the oxidative decarboxylation of 3-methyl FAs has been resolved in recent years. Figure 105-2 depicts the structure and enzymology of the peroxisomal fatty acid alpha-oxidation system. Phytanic acid first undergoes activation to phytanoyl-CoA and then passes the peroxisomal membrane probably as phytanoyl-CoA via a carrier protein. Once inside peroxisomes, phytanoyl-CoA undergoes hydroxylation, followed by cleavage to pristanal and formyl-CoA. Subsequently, pristanal is converted into pristanic acid, which is then activated to pristanoyl-CoA.

As discussed above, pristanoyl-CoA undergoes three cycles of beta-oxidation in peroxisomes after which the products are shuttled to mitochondria for full oxidation to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Most enzymes involved in peroxisomal fatty acid alpha-oxidation and their encoding genes have been identified with the exception of pristanal dehydrogenase (see (9) for review). Interestingly, the alpha-oxidation system can handle both stereoisomers of phytanic acid including (3S)-phytanic acid and (3R)-phytanic acid with (2S)-pristanoyl-CoA and (2R)-pristanoyl-CoA as products, respectively. Since the peroxisomal beta-oxidation system only handles (2S)-FAs, (2R)-pristanoyl-CoA first needs to be converted into (2S)-pristanoyl-CoA, which requires the enzyme AMACR (see Figure 105-4).

### 105.2.5 Glyoxylate Detoxification

Glyoxylate is a toxic metabolite. Under normal conditions, glyoxylate is rapidly converted into glycine via the peroxisomal enzyme alanine glyoxylate aminotransferase (AGT). In hyperoxaluria type 1 this enzyme is deficient, and glyoxylate accumulates, followed by oxidation to oxalate or reduction to glycolate (Figure 105-5). Oxalate rapidly precipitates as calcium oxalate with severe consequences for the tissues involved.

## 105.3 ADDITIONAL PEROXISOMAL FUNCTIONS

It should be pointed out that peroxisomes catalyze a number of additional metabolic functions. One such function involves the oxidation of L-pipecolic acid, which is a product of L-lysine. Although the precise metabolic route from L-lysine to L-pipecolic acid and onward has not been fully resolved yet, it is clear that L-pipecolic acid is degraded via the peroxisomal enzyme L-pipecolate oxidase.

Recent studies have also revealed that the enzyme bile acid-CoA: amino acid N-acyltransferase (BAAT) is exclusively localized in peroxisomes (12) (Figure 105-1) which implies that formation of taurocholate, glycocholate, taurochenodeoxycholate, and glycochenodeoxycholate is strictly peroxisomal, so that BAAT-deficiency is actually a peroxisomal disease (see below).

**FIGURE 105-5** Peroxisomes and the detoxification of glyoxylate to glycine as mediated by the peroxisomal enzyme AGT and the subsequent breakdown of glycine in mitochondria. In case of a deficiency of AGT, glyoxylate accumulates and is either reduced to glycolate which can be readily excreted via the urine, or oxidized to oxalate which precipitates in the presence of calcium (calcium oxalate stones). See text for further details.

Until recently it was generally assumed that peroxisomes play a major role in the biosynthesis of isoprenoids including cholesterol, since enzymes like mevalonate kinase, phosphomevalonate kinase, and mevalonate pyrophosphate decarboxylase were claimed to be localized in peroxisomes. Recent studies, however, have indicated that all these enzymes are in fact localized in the cytosol (see (9) for review). Based on these results we conclude that isoprenoid biosynthesis does not involve one or more peroxisomal enzymes. Accordingly, mevalonate kinase deficiency can no longer be considered a PD.

## 105.4 BIOGENESIS OF PEROXISOMES

The essential features of peroxisome biogenesis in humans have been nicely worked out in recent years, thanks to the work on lower eukaryotes, including bakers yeast (*Saccharomyces cerevisiae*). Since peroxisomes lack their own DNA, like mitochondria do, the genetic code for both the peroxisomal membrane proteins (PMPs) and peroxisomal matrix proteins is contained in nuclear DNA. The generally accepted idea is that peroxisomes start their life in the endoplasmic reticulum (ER) where an initial pre-peroxisomal structure is formed which buds off and develops into a full grown functional peroxisome. Large collections of proteins, which play a crucial role in the formation of peroxisomes, have been identified in recent years and are named “peroxins.” The corresponding genes are PEX genes. In humans at least 12 different PEX genes and the corresponding peroxins have been identified whereas in different yeasts quite a few more have been found (13). Although the

fine details of peroxisome biogenesis still need to be resolved, the general notion is that PEX3 plays an essential role in the initial phase of peroxisome biogenesis, i.e. the formation of the preperoxisomal vesicle in the ER (Figure 105-6). Once this initial vesicle is formed, different PMPs are inserted into the membrane of this vesicle, a process mediated by PEX19, which has been shown to bind multiple PMPs. Binding between PEX19 and different PMPs is supposed to happen in the cytosol after which these PMPs are specifically targeted to the membrane of the preperoxisomal vesicle with PEX3 acting as the docking partner for PEX19 thus ensuring specific targeting of PMPs to the preperoxisomal vesicle. Once this is done, the vesicle is ready to be filled up with various matrix proteins the majority of which are actually enzymes required for the execution of the different metabolic functions of peroxisomes. In order to target these proteins specifically to peroxisomes, peroxisomal matrix proteins contain one of two different peroxisomal targeting signals (PTS). The *first* one (PTS1) is made up of a set of three amino acids located at the carboxy-terminal end of the protein. These amino acids are: serine, lysine, and leucine at position 3, 2 and 1 of the carboxy-terminal end of the protein respectively. Some variants of this SKL theme are permitted.

The *second* signal (PTS2) involves a stretch of nine amino acids located at the amino-terminal end of peroxisomal matrix proteins. Most proteins possess a PTS1 signal. The PTS1 and PTS2 signals are recognized by soluble receptors, i.e. PEX5 and PEX7, respectively, in the cytosol (Figure 105-6). The two receptors loaded with “cargo” are recognized by the PEX13/PEX14 complex located in the peroxisomal membrane (Figure 105-6) and then release their cargo, i.e. a PTS1—or PTS2—protein followed by their extrusion into the peroxisome interior. This complicated process requires the active participation of a number of peroxins, including PEX2, PEX10 and PEX12 as well as PEX1 and PEX6.

After releasing their cargo PEX5 and PEX7 cycle back into the cytosol where they can bind another PTS1 or PTS2 protein. In addition to the peroxins described above, additional peroxins are involved in other aspects of peroxisome biogenesis including peroxisome division (PEX11-alpha, PEX11 beta, PEX11-gamma and DLP1). Defects at the level of most of these different peroxins have been identified as described in detail below.

### 105.4.1 Peroxisomal Disorders

The different PDs identified thus far are listed in Table 105-1 and are usually classified into two distinct groups including: (1) the peroxisome biogenesis disorders (PBDs) and (2) the disorders of peroxisome function. The latter group comprises of single peroxisomal enzyme deficiencies although in X-linked adrenoleukodystrophy (X-ALD) it is not an enzyme which is functionally defective but a transport protein as discussed in detail below.

**FIGURE 105-6** Biogenesis of peroxisomes in humans. Peroxisomes start their life in the ER but may also form from preexisting peroxisomes. The peroxin PEX3 is essential for this initial phase of peroxisome biogenesis in which a pre-peroxisome is generated. The peroxins PEX16 also plays a role—albeit it unresolved yet—in this initial phase of peroxisome biogenesis. Subsequently, the PMPs are inserted into this pre-peroxisomal vesicle with a key role for the cytosolic cycling receptor PEX19. The next phase is the import of matrix proteins mediated by PEX5 for PTS1 proteins and PEX7 for PTS2 proteins, respectively. Next, peroxisomes undergo proliferation and division. The division of peroxisomes involves three distinct sequential steps including elongation of peroxisomes, membrane constriction, and finally fission of peroxisomes. The proteins DLP1, mammalian fission 1 and mammalian mitochondrial fission factor are involved in this process. Remarkably, the latter three proteins do not only play a role in the fission of peroxisomes but also in the fission of mitochondria. With respect to the elongation of peroxisomes different PEX11 proteins are involved. See text for further details.

(1) The PBD group is heterogeneous in itself and is subclassified into two distinct subgroups A and B. The underlying basis for the subclassification is the fact that in the group A disorders both the PTS1- and PTS2-import pathways are disturbed (see [Figure 105-6](#)), whereas in PBD-group B disorders only the PTS2-pathway is affected. Importantly, the clinical signs and symptoms of patients with a PBD-group A disorder are widely different from those of patients affected by RCDP Type 1 which is so far the only PBD-group B disorder. Until recently, PBD-group A was comprised of three distinct PDs including ZS, neonatal adrenoleukodystrophy (NALD) and infantile Refsum disease (IRD). The discovery, however, of phenotypes in between ZS and NALD, and NALD and IRD, respectively, plus the identification of additional phenotypes different from ZS, NALD, and IRD has prompted institution of a new name, i.e. “Zellweger spectrum disorders” (ZSDs). An additional benefit of this new nomenclature is that names like NALD and IRD will disappear which is good since they continue to generate confusion since they suggest that there is a link with X-ALD and RD respectively.

**105.4.1.1 Zellweger Syndrome (MIM 214100).** ZS was first described as cerebro–hepato–renal syndrome in 1964 by Bowen, Lee, Zellweger and Lindenberg (1) in two pairs of siblings. The clinical presentation of ZS is dominated by: (1) typical cranial facial dysmorphism and (2) severe neurological abnormalities. Facial

features include a large anterior fontanel with widely spaced sutures (96%), a broad full forehead (97%), micrognathia (100%), external ear deformity (97%), low and broad nasal bridge (100%), shallow orbital ridges (100%), and redundant skin folds of the neck (100%). The neurological picture is dominated by a profound truncal and peripheral hypotonia (99%), with poor sucking (97%) requiring gavage feeding, absence of visual and auditory responses, and seizures usually after the second week of birth and depressed neonatal and deep tendon reflexes. Other neurological abnormalities include an abnormal Moro response (100%), hypo/areflexia (98%) and epileptic seizures (92%). Ocular abnormalities include corneal clouding, congenital cataracts and glaucoma. Brushfield spots and retinitis pigmentosa (RP) with extinguished electroretinograms are frequently found. Hepatomegaly and cardiac defects are also present. Calcific stippling of the epiphyses visible on X-ray examination and small renal cysts that cannot be detected by echography have been reported. Brain abnormalities in ZS include a very specific cortical dysplasia with polymicrogyria and pachygyria in the perisylvian region, neuronal heterotopia, migration defects of Purkinje cells and discontinuations in the principle nucleus of the inferior olivary complex. There is dysmyelination rather than demyelination of the cerebral white matter. All these abnormalities can be diagnosed by MRI. More than 90% of ZS patients show postnatal growth failure.

Patients with ZS do not develop any psychomotor skills and usually die before 12 months of age.

**105.4.1.2 Neonatal Adrenoleukodystrophy (MIM 202370).** Patients with NALD have a somewhat less severe phenotype than ZS patients. They might be present at birth with severe hypotonia, absence of visual and auditory responses and seizures but the typical cranial facial dysmorphism observed in ZS is absent. RP and hepatomegaly are frequently found, however, brain abnormalities may include polymicrogyria, but without the severe cortical dysplasia seen in ZS. When NALD patients survive beyond 3 years of age, brain MRI may show progressive demyelination in addition to preexisting dysmyelination and is associated with rapid neurological deterioration. Occasionally NALD patients may develop some psychomotor achievements during the first year of life, but they remain severely retarded. Age of death is usually between 2–3 years of age. Needless to say that NALD and X-ALD are completely different diseases which only share a few abnormalities including demyelination of the central nervous system (CNS) white matter, atrophy of the adrenal cortex, ballooned adrenocortical cells, and splinter-like lamellar elements composed of electron-dense leaflets separated by a clear space which initially prompted the name NALD.

**105.4.1.3 Infantile Refsum Disease (MIM 266510).** Patients with IRD may have external features reminiscent of ZS but do not show disordered neuronal migration and no progressive white matter disease. The patients originally described as IRD had persistent jaundice and liver disease in the first 3–6 months of life. Later it became clear that there was also psychomotor retardation and RP. Remarkably, the liver disease recovered over the years, whereas the other abnormalities remained, including severe mental retardation, major behavioral problems, progressive blindness due to retinopathy, and peripheral deafness. In general, survival of IRD is variable. Most patients with IRD, however, do reach adolescence, and several even have reached adulthood. The clinical severity is remarkably variable. Some patients may have moderate learning disabilities with deafness and visual impairment that has sometimes led to the diagnosis of Usher syndrome (14) while others have severe and more global neurological handicaps.

**105.4.1.4 Other Phenotypes.** In the last few years a number of patients have been described with phenotypes different from ZS, NALD and IRD (6,7,14–18). Several of these patients have shown mild neurological symptoms, notably cerebellar ataxia, and peripheral neuropathy since adolescence with relative intactness of cognitive functions. From the second decade onward most of these patients end up developing obvious neurologic deterioration characterized by tetraparesis, dystonia, ataxia, and cognitive decline. Brain MRI frequently shows signs of cerebral demyelination mostly of the periventricular white matter. Initially progression of the neurological symptoms may be slow, but patients then aggravate

rapidly to a vegetative state or death. Remarkably, in recent years several patients with isolated cerebellar ataxia have been described who turned out to have a peroxisome biogenesis defect (6,7).

**105.4.1.5 Rhizomelic Chondrodysplasia Punctata Type I (MIM 215100).** RCDP Type I is a PD completely different from the ZSDs described above and is characterized by a disproportionally short stature primarily affecting the proximal parts of the extremities, typical facial appearance including a broad nasal bridge, epicanthus, high arched palate, dysplastic external ears and micrognathia, congenital contractures, characteristic ocular involvement, dwarfism and severe mental retardation with spasticities. Roentgenological studies have shown a series of abnormalities including symmetrical shortening of femur and humerus with irregular and broad metaphyses, calcific stippling mainly of the epiphyses, absent capital femur epiphysis, coronal clefts of vertebrae, increased intravertebral disc spaces, cupping of dorsal ribs, and a barrel-formed thorax. Neurological impairments include truncal hypertonia, spastic tetraplegia and epilepsy. Patients usually develop profound mental retardation and disproportionate growth failure before 3 years of age. In contrast to earlier views patients usually survive beyond 1 year of age. A subset of patients with RCDP has a milder clinical phenotype with less severe neurological impairment involving moderate to severe mental retardation with motor problems and nearly normal skeletal findings. No abnormalities on MRI are seen in the patients with milder phenotypes whereas delayed myelination, ventricular enlargement, and increased subarachnoid spaces, supratentorial myelin abnormalities, and progressive cerebellar atrophy are observed in patients with a severe phenotype of RCDP Type I (19).

## 105.4.2 Biochemistry and Molecular Basis of the ZSDs

In ZSD patients essentially all metabolic functions of peroxisomes are impaired due to the fact that proper peroxisome formation is disturbed as discussed in more detail below. This implies: (1) deficient beta-oxidation of FAs, normally handled by peroxisomes including VLCFAs like C26:0, pristanic acid, di- and trihydroxycholestanic acid, and tetracosahexaenoic acid (C24:6( $\omega$ -3)), (2) deficient alpha-oxidation of phytanic acid, (3) impaired synthesis of etherphospholipids including plasmalogens, (4) impaired degradation of glyoxylate, and (5) deficient oxidation of L-pipecolic acid. In general, all these abnormalities at the cellular level, are reflected in clear abnormalities in blood either in plasma (VLCFAs, pristanic acid, phytanic acid, di- and trihydroxycholestanic acid, pipecolic acid, plus C24:6 and C22:6), or in blood cells, notably erythrocytes (plasmalogens, C24:6 and C22:6). Also in urine abnormalities are usually found (oxalate, glycolate). In general, the abnormalities observed in plasma and/or erythrocytes reflect the extent of the

defect in peroxisome biogenesis especially with respect to (1) the VLCFAs, notably C26:0 in plasma and (2) plasmalogens in erythrocytes. Indeed, plasma C26:0 levels are in general highest in classical ZS patients and much lower in ZSD patients at the mild end of the spectrum whereas the reverse is true for the erythrocyte plasmalogens which may be virtually fully deficient in classical ZS but normal in milder ZSD patients. Phytanic acid and pristanic acid are solely derived from exogenous sources and may vary from normal to hugely elevated depending upon dietary intake. Di- and trihydroxycholestanic acid synthesized from cholesterol in the liver are in general higher in ZS patients but there are large variations between patients independent of phenotype (20). Finally, L-pipecolic acid is a useful marker of peroxisome dysfunction although again levels in individual patients vary widely independent from the phenotype (21).

Fibroblasts from patients have become the material of choice for diagnostic purposes since all metabolic functions of peroxisomes except bile acid synthesis and L-pipecolic acid oxidation are expressed in these cells. Furthermore, the morphology of peroxisomes can be studied easily using immunofluorescence microscopy analysis using antibodies against peroxisomal matrix proteins like catalase and PMPs like PMP70. Both antibodies are commercially available. Liver biopsies have long remained the golden standard for the diagnosis of patients but biopsies are no longer required nowadays although in some cases morphological analysis of peroxisomes in liver biopsy specimens has remained important. Lymphoblasts can also be used for diagnostic purposes.

In recent years, much progress has been made in the elucidation of the genetic basis of the different peroxisome biogenesis disorders. Earlier studies had already shown that the genetic basis of the ZSDs is very heterogeneous. This was concluded from the so-called complementation studies, which involves fusion of fibroblasts of two different patients with the same abnormality such as a defect in peroxisome biogenesis so that hybrid cells are generated containing nuclei from the two patients' fibroblasts. These cells are called heterokaryons. If the defective genes in the two patients' cell lines are different, one would expect restoration of peroxisome formation whereas in the other case when the mutant genes are identical, no complementation would occur. This is most easily done using catalase immunofluorescence. Collaborative studies involving laboratories in Japan (Gifu), USA (Baltimore) and The Netherlands (Amsterdam) have led to the identification of a total number of 12 different complementation groups (CGs) (22).

With the recent identification of *PEX26* as the defective gene in complementation group 8 (CG8) by Matsumoto et al. (23,24), the *PEX* genes underlying each of the CGs have all been identified now (Table 105-2). Most CGs include only a few patients. One exception to this rule is CG1 with *PEX1* as the defective gene, which is by

**TABLE 105-2** Frequency Distribution of *PEX* Gene Defects among 613 Patients Diagnosed with a ZSD

<i>PEX</i> Gene	Number of Patients Cell Lines Analyzed	Frequency (%)
<i>PEX1</i>	358	58
<i>PEX2</i>	23	4
<i>PEX3</i>	3	<1
<i>PEX5</i>	13	2
<i>PEX6</i>	97	16
<i>PEX10</i>	19	3
<i>PEX12</i>	54	9
<i>PEX13</i>	10	1
<i>PEX14</i>	3	<1
<i>PEX16</i>	8	1
<i>PEX19</i>	4	<1
<i>PEX26</i>	21	3

Data taken from Ebberink et al. *Hum. Mutat.* 2011 32, 59–69.

far the largest CG containing more than half of all Zellweger spectrum patients. In our own series of >600 Zellweger spectrum patients thereby excluding RCDP, 358 patients (58%) were found to belong to CG1 (*PEX1*) followed by 97 (16%) in CG4 (*PEX6*), and 54 (9%) in CG3 (*PEX12*) (25).

If all mutant *PEX* alleles are taken together, >100 mutations have been so far described in literature (25). In many cases mutations are private being restricted to single families only. Most mutations have been described in the *PEX1* gene (>80). Among these mutations a few common mutations have been identified. Most common is the missense mutation in exon 15 (c.2528G > A) leading to the substitution of the glycine at position 843 of *PEX1* by an asparagine (p.G843D) in the second ATP-binding domain. Patients homozygous for this mutation show the mild Zellweger spectrum phenotype (NALD/IRD). The frequency of the c.2528G > A (p.G843D) allele ranges from 0.25 to 0.37 in different cohorts. In our own cohort of *PEX1* mutated patients we found an allele frequency of 0.41 out of which 12% of the patients were homozygous and 17% were compound heterozygous for the c.2528G > A allele. The second most common mutation is a T insertion in exon 13 (c.2097\_2098insT), first described by Maxwell et al. (26) and Collins and Gould (27), which results in a frame shift and low steady state *PEX1* mRNA levels, presumably caused by nonsense mediated RNA decay. At the protein level it leads to truncation of the *PEX1* protein within the second AAA domain, abolishing *PEX1* function completely. In its homozygous form the mutation results in the severe Zellweger phenotype. Together, these two mutations account for around 50–60% of all mutant *PEX1* alleles. Interestingly, the mutation c.2528G > A encodes a *PEX1* mutant protein, which allows residual import for peroxisomal matrix proteins. The mutation seems to result in a misfolded

protein, which is more stable at lower than at higher temperatures, which explains the mosaic catalase immunofluorescence pattern at 37°C whereas a virtually normal pattern is observed at 30°C (28,29). The G843D amino acid substitution most likely disrupts the interaction between PEX1 and PEX6 (30,31).

### 105.4.3 Biochemistry and Molecular Basis of RCDP

RCDP type 1 is characterized by the deficiency of plasmalogens in all tissues including erythrocytes (32). Furthermore, plasma phytanic acid levels are increased in age and diet dependent manner. These data immediately suggested that at least two peroxisomal functions were impaired in RCDP type 1, including (1) plasmalogen biosynthesis and (2) phytanic acid alpha-oxidation. Detailed studies have shown that several peroxisomal enzymes are indeed deficient in RCDP type 1, including (1) DHAPAT, (2) alkyl-DHAP synthase, (3) phytanoyl-CoA hydroxylase, and (4) peroxisomal thiolase. The underlying basis for this surprising combination of defects in a single genetic disease became clear when the gene defective in RCDP type 1 was discovered. The gene involved is the *PEX7* gene, which codes for the PTS2 receptor. Alkyl-DHAP synthase, phytanoyl-CoA hydroxylase, and peroxisomal thiolase are all PTS2 proteins, which immediately explains their deficiency in RCDP type 1. The peculiar finding that DHAPAT is also deficient in RCDP type 1 has been resolved by De Vet et al., who found that alkyl-DHAP synthase and DHAPAT form a complex within peroxisomes so that DHAPAT is unstable in the absence of alkyl-DHAP synthase (33).

Two large studies have appeared on the molecular basis of RCDP type 1, which show many different mutations, although a single mutation (c.875T > A (p.L292X)) accounts for about half of the mutant *PEX7* alleles in RCDP patients (34,35). Haplotype analysis revealed that this mutation is on the same background, strongly suggesting a founder effect in Northern Europeans.

### 105.4.4 Treatment

At present there is no curative treatment for both the ZSDs and RCDP type 1. Treatment with docosahexaenoic acid (C22:6(ω-3)) has been claimed to be beneficial to patients (36), but studies in larger series of patients have shown no relevant clinical improvement (37). Inspired by the fact that the bile acid intermediates dihydroxycholestanic acid are considered very toxic to liver cells and may very well be responsible for the cholestasis frequently observed in ZSD patients, oral bile acid therapy has been tried in a few patients only with some therapeutic benefit (38,39). Indeed, Setchell et al. (39) were the first to report on such a bile acid treatment in a 6-months-old Zellweger patient. This patient received

the primary bile acids cholic acid and chenodeoxycholic acid (100 mg each/day) orally. A significant improvement in biochemical indices of liver function occurred with a normalization of the serum bilirubin and liver enzymes and a histological improvement in the extent of inflammation and bile duct proliferation and disappearance of canicular plugs. Steatorrhea improved as well and was accompanied by improvement in growth. Importantly, plasma and urinary C<sub>27</sub>-bile acid intermediates decreased with treatment. Despite the observed improvements the patient died at 1 year of age. Maeda et al. (38) have reported beneficial effects of ursodeoxycholic acid (UDCA) and chenodeoxycholic acid (CDCA) treatment in two Japanese patients with Zellweger syndrome with the combination of UDCA and CDCA showing the best results. At present we are conducting a larger oral bile acid therapy study in our cohort of mildly affected ZSD patients (18).

In RCDP type 1 no curative treatment has been devised as well. Interestingly, Brites et al. (40) has found that in the *PEX7* knockout mouse model, which is a mouse model for RCDP type 1, a diet enriched with 1-O-octadecyl-*rac*-glycerol can restore plasmalogen levels in the peripheral tissues of the RCDP mouse but not in the CNS (40,41). This is most likely due to the inability of AG to cross the blood-brain barrier. When supplied prior to the occurrence of pathological changes, i.e. during pregnancy, the AG diet was found to ameliorate the peripheral pathology observed in the RCDP type 1-knockout mice, which is related to the extent to which plasmalogen levels are restored. This diet is currently being evaluated in patients with RCDP type 1 (Poll-The et al. work in progress).

## 105.5 SINGLE PEROXISOMAL ENZYME DEFICIENCIES

### 105.5.1 X-linked Adrenoleukodystrophy (MIM 300100)

X-ALD is a collective term, which includes a range of different phenotypes all due to mutations in *ABCD1* that codes for a protein named ALDP. The abnormalities involved in X-ALD primarily affect the CNS, adrenal cortex and Leydig cells of the testes. X-ALD comes in two main phenotypes including the cerebral demyelinating form of X-ALD and adrenomyeloneuropathy (AMN). AMN and cerebral ALD may occur in the same family, and there is no apparent correlation between the X-ALD phenotype and the mutations in the *ABCD1* gene. Cerebral ALD is characterized by a rapidly progressive inflammatory demyelination within the brain resulting in severe cognitive and neurologic disability and a vegetative state within 2–5 years after onset of symptoms and death thereafter. This phenotype is most common during childhood (childhood cerebral ALD: CCALD) and adolescence (adolescent cerebral ALD: ACALD).

**105.5.1.1 Cerebral ALD.** Cerebral ALD is the most severe type of X-ALD. Indeed, male newborns with bonafide mutations in *ABCD1* have 35–40% risk to develop childhood cerebral ALD between 5 and 12 years of age. Furthermore, 20% of patients initially showing the AMN phenotype develop cerebral ALD later in life so that the lifetime risk to develop cerebral ALD amounts to 55–60%. The typical presentation of CCALD is that of a boy presenting with learning disabilities, and behavioral problems, often diagnosed as attention deficit hyperactivity disorder may actually respond to stimulant medication (42). This is followed by neurological deterioration with cognitive decline, behavioral problems, impaired central auditory discrimination, cortical blindness, often seizures and quadriparesis. Patients may be completely normal until they develop cerebral demyelination visible on brain MRI (abnormal hypersignal of white matter on T2 and FLAIR sequences, hyposignal of white matter on T1 sequences). Usually, the initial lesions involve either the splenium of the corpus callosum and then extend into the adjacent white matter of the parieto-occipital loops or alternatively the genu of the corpus callosum and then extend into the white matter of the frontal loops. Initial demyelinating lesions may also occur in the pyramidal tracts, within the brain stem or internal capsule and then extend into the centrum semiovale (frontal white matter). The cerebral demyelinating lesions can be asymmetric, particularly when previous head trauma or even stroke seems to have initiated the onset of cerebral ALD. Initially, demyelinating lesions are not inflammatory and progress slowly. The patients then have virtually no neurological symptoms except mild cognitive dysfunction. Subsequently, when the disease becomes inflammatory rapid progression sets in and the patients enter into an active phase of devastating neurologic and cognitive deterioration that include emotional lability, hyper active behavior, school failure, and either visuo-spatial impairment or frontal syndrome according to the sites of the demyelinating lesions. This ends in the rapid development of motor symptoms (hemiplegia or quadriparesis), impaired central auditory discrimination, quadrantsopia and then loss of vision, and often seizures, which is subsequently followed by a vegetative state within 2–4 years, and to death at varying intervals thereafter.

**105.5.1.2 Adrenomyeloneuropathy.** The first symptoms of AMN usually appear when patients are between 20 and 30 years of age. AMN males develop progressive stiffness and weakness of the legs, impaired vibration sense in the lower limbs, sphincter disturbances, and impotence. Approximately two third of AMN patients also show clinical signs of a peripheral neuropathy which is usually not prominent and all males with AMN frequently have typical scanty scalp hair that often develops during adolescence. This hair abnormality can also be found in heterozygotes. The evolution of AMN in adult

males is quite variable. In two third of AMN patients the neurological disability progresses slowly. Within 10–15 years motor disability becomes more severe and requires the use of a cane or a wheelchair. However, 35% of patients with AMN have a marked progression of their myelopathy within the first 3 years after the onset of clinical symptoms. Adrenal insufficiency (Addison's disease) is present in approximately two third of males with AMN and in <1% of heterozygous women.

**105.5.1.3 Addison's Disease Only.** Adrenal insufficiency may be the only sign of X-ALD in approximately 10% of affected individuals (43). The signs include unexplained vomiting, weakness or coma. Some individuals have hyper-pigmented skin, due to increased ACTH secretion. Biochemical evidence of an adrenal insufficiency can be present for up to 2 years before the development of clinical signs. Some males with bonafide *ABCD1* gene mutations have been reported without clinical features of adrenal insufficiency. Most individuals, however, who present with isolated adrenal insufficiency, develop some form of X-ALD. In boys presenting with Addison's disease prompt evaluation for X-ALD is important because early diagnosis is likely to improve outcomes from therapy including hematopoietic stem cell transplantation (see below).

## 105.5.2 Female Carriers

Female carriers may be symptomatic depending upon the pattern of X-chromosome inactivation (44). Affected individuals typically present with mild spastic paraparesis in mid-adulthood. AMN-like symptoms affect up to 50% of female heterozygotes in middle age or later although the development of cerebral form of X-ALD is uncommon. Adrenal insufficiency is rare in females (1%).

## 105.5.3 Biochemistry and Molecular Basis of X-ALD

Plasma VLCFA analysis has proven to be an exceptionally robust initial biomarker for X-ALD, especially when the algorithm, as developed by Moser and coworkers (45) is used which is based on the analysis of three parameters including C26:0, C24:0/C22:0 and C26:0/C22:0. Whereas in males diagnosis on the basis of plasma VLCFAs is unambiguous, this is not true for heterozygotes. Indeed, in approximately 20% of obligate heterozygotes plasma VLCFAs are entirely normal, which immediately suggests that additional work has to be done to obtain a conclusive answer. Mutation analysis is the most reliable method for the identification of heterozygotes at least when the mutation in the family has been defined in an affected male or obligate heterozygote relative. If the female in question, however, has no family history of X-ALD, mutation analysis plus detailed studies in fibroblasts, notably immunofluorescence microscopy analysis of ALDP may be needed to obtain a definitive answer.

The X-ALD gene covers 19.9kb, contains 10 exons, and codes for a 745 amino acid peroxisomal transmembrane protein with the general structure of an ATP-binding cassette transporter. Mutation analysis of the *ABCD* gene in X-ALD patients has so far revealed 581 different mutations (<http://www.X-ALD.nl>). Of these mutations, 295 (51%) are missense mutations, 166 (29%) frame shift mutations, 67 (12%) nonsense mutations, 35 (6%) amino acid insertion/deletions, and 18 (3%) larger deletions of one or more exons. Importantly, 78% of all nonrecurrent *ABCD1* mutations resulted in the absence of ALDP (<http://www.X-ALD.nl>). As stated above there is no apparent genotype/phenotype correlation for X-ALD as exemplified by the presence of five different phenotypes in six male patients of a family with a destabilizing missense mutations (p.Pro484Arg) (46).

### 105.5.4 Treatment

It is crucially important to provide adrenal steroid hormone therapy for every ALD patient with adrenal cortical insufficiency. Almost all affected boys, and 60% of men with AMN have impaired adrenal reserve (47). Consequently, all patients diagnosed should undergo an ACTH stimulation test to detect frank adrenal failure or subclinical decreased adrenal cortical reserve. If left untreated, these patients may succumb to adrenal crises. However, adrenal steroid hormone therapy does not appear to alter the course of neurological deterioration. Based on the success of dietary restriction of phytanic acid in RD, a diet low in C26:0 was tried in X-ALD patients without success. Subsequently, a dietary therapy, based on supplementation with oleic acid and erucic acid (GTO/GTE) diet was tried, again without success. It should be noted that the GTO/GTE oil, also called Lorenzo's oil, is able to normalize the plasma levels of C26:0 after 3–5 weeks. This effect is most likely mediated through the competition of C18:1 and C22:1 with C18:0 and C22:0 for chain elongation. This pharmacological effect occurs in peripheral tissues in particular in the liver but apparently C18:1 and C22:1 are unable to cross the blood–brain barrier so that chain elongation of long-chain fatty acids to VLCFAs is not inhibited by C18:1 and C22:1 in the brain. The diet might have a preventive effect—albeit very limited—on the development of CCALD when given to boys before the age of 5 years. In any case this diet does not prevent the onset of CCALD and boys treated with Lorenzo's oil must have regular brain MRI examination, at least up to the age of 12 years to detect the early-onset of cerebral demyelination.

Allogeneic hematopoietic stem cell transplantation (HCT) (also known as bone marrow transplantation) is the only treatment that can arrest or even reverse cerebral demyelination provided the procedure is performed at an early stage of the disease and this point is absolutely

crucial (48–51). When patients have already obvious neurologic signs and extensive demyelinating lesions (Loes score >10) HCT has no effect and patients may even aggravate following the HCT procedure. The beneficial effect of HCT is mediated through the replacement of brain microglia in the patient by bone marrow derived myelo-monocytic cells from the donor that cross the blood–brain barrier and differentiate into microglia with normal ALDP function. HCT requires the availability of a HLA-matched donor who can be a nonaffected brother or sister, an unrelated donor or a cord-blood donor. In children the mortality risk of HCT with an unrelated or a cord-blood donor is approximately 15%. The mortality risk of HCT under the same conditions is 40% in adults. Although more than 200 X-ALD patients have now been transplanted successfully (52) and a 20-years follow-up of treated patients has confirmed the beneficial effect of allogeneic HCT in X-ALD definitively, the procedure remains associated with serious limitations in particular with respect to the availability of donor(s) and the mortality and morbidity risks of the procedure. Human stem cell (HSC) gene therapy will certainly be an alternative to allogeneic HCT in the near future. HSC gene therapy relies upon the reinfusion of the HSCs of the patient, which have been corrected ex vivo. Two X-ALD patients have recently been successfully treated by HSC gene therapy (53). The efficacy of the procedure in arresting the cerebral demyelination is identical to allogeneic HCT. In the study by Cartier et al. the HSCs were corrected ex vivo by a HIV-1 derived lentiviral vector expressing the *ABCD1* gene.

### 105.5.5 Acyl-CoA Oxidase Deficiency (MIM 264470)

Acyl-CoA oxidase (ACOX) deficiency first described in 1988 has so far been described in about 30 patients in literature. The clinical, biochemical and mutational spectrum of a cohort of 22 patients, affected by ACOX-deficiency has recently been published by us (54). Before the enzyme and molecular defect was identified, ACOX deficiency was referred to as pseudo-neonatal adrenoleukodystrophy since the clinical picture of the first patients described by Poll-Thé et al. (55) resembled that of patients affected by neonatal adrenoleukodystrophy as published by Kelley et al. (56) in 1986.

All patients identified so far had psychomotor retardation, but did acquire limited skills, including the ability to sit and stand up unsupported, voluntary control of hand function, and limited speech. In most patients (83%), however, there was loss of motor achievements with a mean age of regression of 28 months. Brain imaging (MRI and/or CT) revealed cerebral and/or cerebellar white matter abnormalities in all patients investigated (12/12). Three of these patients showed neocortical dysplasia. Other abnormalities include hypotonia (97%), seizures (91%), visual system failure (78%), impaired

hearing (77%), facial dysmorphism (50%), hepatomegaly (50%) and failure to thrive (37%).

Interestingly, two adult patients affected by ACOX1 deficiency have recently been described (57). Early developmental milestones were normal in these patients. At age 10, one patient was noted to have scoliosis and a clumsy-like hand. His gait showed progressive unsteadiness until the age of 28 when he became wheelchair bound. He had some urinary and fecal urgency. At the time of diagnosis (52 years of age), he had mildly impaired cognitive function. His memory was poor, but he was well oriented and could give an adequate description of his present problems. The visual acuity in the right eye was restricted to hand movements. He had small lens opacities. Retinitis pigmentosa was observed in both fundi. There was no optic disc pallor. Gaze evoked nystagmus on upgaze, downgaze and lateral gaze was present. He had a slurring dysarthric speech but near normal tongue movements. He had a jerky head tremor. There was some dystonic posturing of his arms and ataxia was seen on finger–nose testing. There was spastic paraparesis in the lower limbs. Sensation was normal with all modalities. Brain MRI showed profound atrophy of the brain stem and cerebellum, particularly evident in the pons, and modest cerebral atrophy. No other abnormality was seen. Nerve conduction studies were normal. Electroretinogram showed a virtually absent response from either eye. His sister was similarly affected at 55 years of age with onset of ataxia at 8 years.

**105.5.5.1 Biochemical and Molecular Basis of ACOX Deficiency.** Determination of the peroxisomal biomarker panel in plasma of ACOX-deficient patients has revealed that the abnormalities are restricted to the accumulation of VLCFAs that follow logically from the fact that the enzyme ACOX1 handles the CoA esters of VLCFAs but not of other peroxisomal substrates including pristanic acid and di- and trihydroxycholestanoic acid.

Elevated plasma VLCFA-levels have been found in all patients described in literature with proven ACOX1 deficiency except for one. Indeed, Rosewich et al. (58) described a case of ACOX1 deficiency with normal plasma VLCFAs. Based on the characteristic MRI findings a full study in fibroblasts was performed which revealed clear VLCFA abnormalities in fibroblasts and in addition a marked deficiency of the enzyme ACOX and clear-cut mutations in the ACOX1 gene. This case underlines once more that care should be taken in the interpretation of plasma metabolite results as detailed below.

The molecular basis of ACOX1 deficiency has been worked out by Ferdinandusse et al. (54), which revealed marked genetic heterogeneity with 20 different mutations. Two additional mutations have been published by Suzuki et al. (59).

No treatment options have been described for ACOX1 deficient patients.

## 105.5.6 DBP Deficiency (MIM 261515)

The first patient affected by DBP deficiency was described by Watkins et al. in 1989 (60). Interestingly, at that time it was believed that this patient had a deficiency of the other peroxisomal bifunctional protein, i.e. LBP. It took until 1999 before the true defect in this patient was identified at the level of DBP (61). The patient described by Watkins et al. (60) was born hypotonic and macrocephalic, had made no developmental progress at 6 weeks, continued to seize, remained hypotonic and macrocephalic, and was poorly responsive to stimuli. Fontanels were large and the metopic suture split. There was no cranial facial dysmorphism. Visual and brain stem auditory evoked responses were grossly abnormal. The skeletal survey and renal ultrasound were normal. A brain biopsy at 6 weeks revealed polymicrogyria. Post mortem examination revealed the cause of death to be bronchopneumonia and enteritis with patchy necrosis of the small bowel. Examination of the brain revealed polymicrogyria, demyelination of the white matter in the cerebrum, focal areas of cortical heterotopia, a few foamy macrophages in the perivascular spaces, and cystic degeneration of the periventricular zones. The cerebellum appeared normal. Since then many patients with DBP deficiency have been described. In 2006, Ferdinandusse et al. (62) reported on the clinical and biochemical spectrum of DBP deficiency in 126 patients. The clinical presentation of DBP deficiency is dominated by neonatal hypotonia (98%) and seizures (93%) within the first months of life. Nine patients (15%) were reported to have had infantile spasms at any time. Failure to thrive was observed in 43% of the patients. Visual system failure, including nystagmus, strabismus, or failure to fixate objects at 2 months was reported in 39 patients (54%). In addition, a progressive loss of vision and hearing was noted in 35% and 46% of the patients respectively. Almost none of the patients acquired any psychomotor developments and a few patients who did achieve some limited skills, showed progressive loss of motor achievements. The best achievements scored were head control when held at shoulders in nine patients (15%), sitting without support for more than 5 s in two patients (3%), voluntary reaching for objects and control of hand function in five (8%) and four (7%) patients respectively, and talking over to loose words with comprehension of their meaning in one patient only (2%). External dysmorphism was present in 52 patients (58%) and resembled that of patients with ZS. Frequently described were high forehead, high arched palate, and large fontanel, long philtrum, epicanthal folds, hypertelorism, macrocephaly, shallow super orbital ridges, retrognathia, and low-set ears. A hypoplastic/abnormally shaped thorax was reported in five patients and external genitalia abnormalities were reported in two

additional patients. Brain imaging (either MRI, CT, or ultrasound) showed growth dilatation of the ventricular system in 29% of the patients and neocortical dysplasia in 27%. Delayed maturation of the white matter before 1 year was reported in 16 of 47 patients and after 1 year in five of 14 patients. Demyelination of the cerebral hemispheres occurred in 17% of the patients whereas the occurrence of demyelination of the cerebellar hemispheres was 7%. Cerebellar atrophy was found in one patient and germinolytic cysts were found in 10 patients (20%). The following findings were described in 11 autopsy reports: generalized hyperplasia/atrophy (40%), (perisylvian) polymicrogyria (64%), atrophic/hypoplastic corpus callosum (55%), cerebellar hypoplasia (27%), heterotopic neurons in the white matter (35%) and gliosis (27%). DBP is subdivided into three different types depending on whether it is the complete DBP, which is missing (type I) or only the hydratase (type II) or 3-hydroxyacyl-CoA dehydrogenase component (type III), which is deficient. Kaplan–Meier survival analyses revealed that all type I deficient patients died within the first 14 months of life with 6.9 months as mean age of death. Four type II deficient patients survived beyond the age of 2 years. Two were still alive at the time of the study (62) including the oldest patient within the cohort (162 months). The mean age of death for type II deficiency was 10.7 months. The oldest type III deficient patient was 146 months at the time of the study and from this subgroup 8 patients survived beyond the age of 2 years. The mean age of death was 17.6 months. The immediate cause of death was pneumonia for almost all patients.

**105.5.6.1 Biochemistry and Molecular Basis of DBP Deficiency.** Since DBP plays a key role in the oxidation of multiple FAs including very long-chain fatty acids, pristanic acid, DHCA, and THCA, one would expect accumulation of all these metabolites in plasma from DBP-deficient patients except from pristanic acid and phytanic acid that are derived from exogenous dietary sources only. In the cohort of patients studied by Ferdinandusse et al. (62) VLCFAs were indeed abnormal in virtually all patients except three. In the latter patients phytanic and pristanic acid levels also were normal and the bile acid intermediates DHCA and THCA were undetectable in two of these patients. Phytanic and pristanic acid levels varied considerably in the cohort of DBP-deficient patients. Indeed, phytanic acid levels were increased in 60% of the patients and pristanic acid increased in 44%. In 12 patients no accumulation of DHCA and THCA was found. Detailed studies in fibroblasts from all these patients which includes enzyme activity measurements combined with immunoblot analysis revealed that 27% of the patients had DBP type I deficiency, 28% type II deficiency and 45% type III deficiency. Molecular analysis of the *HSD17B4* gene has revealed a large number of often-private mutations with

only one mutation being more frequent (c.46G → A); allele frequency: 24%). The latter mutation causes glycine to serine amino acid substitution (63), which effectively prevents binding of NAD<sup>+</sup> because of a steric clash (64).

No realistic therapeutic measures for DBP-deficient patients have been described.

### 105.5.7 Peroxisomal Sterol-Carrier Protein X Deficiency

This defect has only been described in a single patient so far (10). Although the name of the deficiency suggests otherwise, the primary abnormality in these patients is the inability to oxidize branched-chain fatty acids like pristanic acid and DHCA and THCA, which indeed accumulate in the patient's plasma. This is explained by the fact that the protein involved sterol-carrier protein X(SCPx) harbors two functional protein domains of which one has a high affinity for sterols whereas the other part actually has 3-ketothiolase activity with preference for the 3-ketoacyl-CoAs of branched-chain fatty acids (see Reference (9) for review).

The patient involved is a 45-years old white man with 28-years history of dystonic head tremor and spasmodic torticollis. He had noticed the start of symptoms for the first time at 7 years of age. At 17 years of age he developed spasmodic torticollis to the left side with dystonic head tremor in stressful situations. On fertility check-up at 29 years of age hypergonadotrophic hypogonadism and azoospermia were diagnosed. One of his two brothers was reported to have similar neurologic complains. Brain MRI showed bilateral hyper intense signals in the thalamus, butterfly-like lesions in the pons, and some lesion in the occipital region. Neurologic examination revealed hyposmia, pathologic saccadic eye movements, and a slight hypoacusis. Deep tendon reflexes were brisk in the arms, but diminished in the lower extremities. There were slight cerebellar signs with level-sided intention tremor and rebound phenomenon.

**105.5.7.1 Biochemistry and Molecular Basis of SCPx-Deficiency.** Analysis of the peroxisomal metabolites in plasma of the patient revealed no abnormalities except for trace amounts of the bile acid intermediates DHCA and THCA, which prompted additional analyses. Interestingly, marked abnormalities were found in the patient's urine, including large amounts of bile alcohols, probably produced via the alternative pathway for bile acid biosynthesis, i.e. the microsomal 25-hydroxylase pathway. The molecular basis of SCPx deficiency has also been determined (10).

### 105.5.8 2-Methyl-Acyl-CoA Racemase Deficiency (MIM 604489)

AMACR deficiency was first described in 2000 (11) in two patients whose clinical presentation was dominated

by the late-onset sensory motor neuropathy. Analysis of the peroxisomal metabolite profile in plasma revealed elevated levels of pristanic acid, DHCA and THCA and phytanic acid, but normal VLCFAs. This suggested a specific defect in the oxidation of branched-chain FAs with branched-chain acyl-CoA oxidase, SCPx, and AMACR as likely candidates (see Figure 105-2). Enzymatic and molecular studies revealed a deficient AMACR activity and mutations in the *AMACR* gene. Interestingly, Setchell et al. (65) described a completely different phenotype of SCPx deficiency dominated by severe liver abnormalities early in life. Recently, Kapina et al. (66) described yet another clinical presentation of SCPx deficiency, characterized by stroke-like episodes and recurrent rhabdomyolysis.

**105.5.8.1 Biochemistry and Molecular Basis of AMACR Deficiency.** The patients identified so far have shown clear abnormalities in plasma, characterized by elevated pristanic acid, DHCA and THCA, but normal VLCFAs. In line with the nature of the enzyme defect (see Figure 105-3) there is virtually exclusive accumulation of the (25R)-stereoisomers of DHCA and THCA, which discriminates AMACR deficiency from all other defects in which DHCA and THCA accumulate. Furthermore, there are clear bile acid abnormalities in urine from patients including the presence of many polyhydroxylated C27-bile acids like in ZSD patients.

## 105.5.9 BAAT Deficiency

Setchell et al. (67) were the first to identify defective bile acid conjugation in humans. This was based on the finding of absent glycine and taurine bile acid conjugates in all biological fluids characterized by the predominance of unconjugated cholic acid and lesser amounts of glucuronide and sulfate conjugates. The patient, an infant of Laotian ethnicity had conjugated hyperbilirubinaemia, mainly sulfate and glucuronide conjugates, fat-soluble vitamin malabsorption, early growth failure and a probably unrelated disorder, i.e. alpha thalassemia that required multiple blood transfusions. Two other patients, a 5-year-old Saudi Arabian boy and his 8-year-old sister, born from a consanguineous marriage, were also reported and had variable degrees of cholestasis. The boy had undergone a Kasai procedure in infancy for wrongly diagnosed biliary atresia whereas the girl was asymptomatic at the time of diagnosis. Liver function tests were either normal or mildly elevated at the time of diagnosis. In 2003, Carlton et al. (68) described the identification of patients from the Amish community with bonafide mutations in the *BAAT* gene. Patients were homozygous for a c.226A > G mutations (M76V) and showed increased serum bile acids which were virtually fully unconjugated. Clinical features of these patients included fat malabsorption, failure to thrive, coagulopathy, pruritus, and chronic upper respiratory infection. They did not have jaundice and had normal serum

gamma-GT concentrations. In 2007, Heubi et al. (69) reported six patients with mutations in the *BAAT* gene. The clinical phenotype included growth delay (3/6), neonatal cholestasis (3/6), including one with fulminant liver failure, and 5/6 with fat-soluble vitamin deficiencies, i.e. vitamin A, E or D. At diagnosis (5 months–19 years) all but one had normal bilirubin and normal or minimally elevated transaminases.

## 105.5.10 Primary Hyperoxaluria Type I (MIM 604285)

The primary hyperoxalurias (PH) are a group of rare inborn errors of glyoxylate metabolism that result in enhanced production of oxalate, mainly by the liver. Oxalate is an end product of metabolism that cannot be further degraded but can only be filtered at the glomerulus and excreted by renal tubules and to some extent the bowel. In case of a defect in glyoxylate breakdown, glyoxylate accumulates and is either oxidized to oxalate or reduced to glycolate. Glycolate is not toxic and can ratherly be excreted into the urine whereas oxalate due to its propensity to participate as calcium oxalate, is toxic to cells, especially in the kidneys which undergo progressive deterioration followed by urolithiasis, nephrocalcinosis, and end-stage renal disease (ESRD). The endogenous overproduction of oxalate with normal dietary oxalate absorption sets these Mendelian disorders apart from the secondary hyperoxalurias, which results from the increased oxalate absorption in the gut. At present, three distinct genetic defects have been identified which cause PH. These include: alanine glyoxylate aminotransferase deficiency (PH-I; gene: *AGXT*; MIM 602485), glyoxylate reductase/hydroxypyruvate reductase deficiency (PH-II; gene: *GRHPR*; MIM 604296) and 4-hydroxy-2-oxoglutarate aldolase deficiency (PH-III; gene: *HOGA1*; MIM 604296). Around 80% of PH patients suffer from PH-I, which is in fact the most severe PH type, often leading to ESRD. Built-up oxalate in the body may lead to oxalate deposition in multiple organs including bone, heart, skin, and retina. In case of a severe AGT deficiency death may occur. The phenotypic variability of PH-I is large, ranging from severe, early-onset oxalosis with early death to adult presentations that resembles idiopathic kidney stone disease. PH-I often goes undetected for years until severe, irreversible kidney damage has occurred. In general, PH-I especially in its severe form has a bad prognosis unless liver (plus kidney) transplantation is performed. PH-I should be considered in all cases of familial stone disease and renal failure of unknown cause.

**105.5.10.1 Biochemistry and Molecular Basis of AGT Deficiency.** AGT catalyzes the alanine-dependent transformation of glyoxylate into glycine with pyruvate as the other product of the AGT enzyme reaction, is localized exclusively in peroxisomes, and has pyridoxal-5-phosphate as cofactor. PH-I is caused by

either deficient or other mistargeted AGT. At present more than 150 different mutations in the *AGXT* gene have been identified.

**105.5.10.2 Laboratory Diagnosis.** Urinary oxalate analysis is the method of choice as initial method to check for PH. In PH-I patients overproduction of oxalate in the liver results in very high urinary oxalate excretion, typically amounting to  $>1 \text{ mmol}/1.73 \text{ m}^2/\text{day}$ . A raised urinary glycolate level is strongly suggestive for PH-I but glycolate may also be entirely normal in PH-I patients. Elevated L-glycerate on the other hand is characteristic for PH-II. Although measurement of AGT enzyme activity in a liver biopsy specimen has long been the golden standard for the diagnosis of PH-I, direct molecular analysis of the *AGXT* gene is rapidly becoming the first choice for diagnosis.

This is due to the fact that in a significant proportion of PH-I patients, AGT enzyme activity is not deficient, at least not in vitro in a liver homogenate prepared after biopsying the patient.

**105.5.10.3 Treatment.** Overall the management of PH-I greatly depends on the degree of renal function. Treatment is directed toward (1) decreasing oxalate production by inhibiting oxalate synthesis and (2) increasing oxalate solubility at a given urinary concentration of oxalate. Most of the efforts have concentrated on ways to increase the solubility of calcium oxalate. High-fluid intake and alkalinization of the urine remains the mainstay of this approach. Indeed, excessive volume is necessary to help excrete the enormous amounts of endogenously produced oxalate. Other helpful therapies may include the use of magnesium oxide (650–1300 mg/day). Furthermore, hemodialysis can remove large quantities of oxalate and its precursors. Attempts in trying to reduce the production of oxalate with succinimide, allopurinol, calcium carbimide, and isocarbazide have been unsuccessful.

Importantly, pyridoxine should be tried in every patient. One third of patients with PH-I respond to pharmacological doses of pyridoxine. Indeed, pyridoxine at the usual daily dose of  $1000 \text{ mg}/\text{m}^2$  body surface area can bring about a substantial reduction in the production and excretion of oxalate except in patients with a pyridoxine-resistant form of the disease. The efficacy of pyridoxine is probably directly related to the extent to which AGT is deficient. Indeed, if there is some residual enzyme activity high levels of pyridoxal-phosphate, which is the obligatory cofactor in the AGT enzyme reaction, may allow residual enzyme activity to operate optimally. In this way, flux through AGT may be considerably stimulated, leading to a reduced production of oxalate. Recent studies have shown a clear association between homozygosity for the two mistargeting mutations Gly170Arg and Phe152Ile, and pyridoxine responsiveness, the reason being that pyridoxine is able to interfere with the mistargeting of AGT to the mitochondrion thereby increasing the residual activity of AGT in peroxisomes from 5 to 10%. In our experience, all patients homozygous for the

Gly170Arg substitution, who had a preserved renal function at the time of diagnosis, were able to preserve renal function throughout the follow-up period when treated accordingly with pyridoxine, a high-fluid intake, and potassium citrate (70).

In cases in which AGT is fully deficient, pharmacological doses of pyridoxine show no effect. These patients will usually develop renal failure, requiring renal transplantation. The overall success rate of this treatment is however low, because the biochemical defect resides in the liver and not in the kidney. As a consequence, a renal transplantation gives only temporary relief, the new organ inevitably becoming obstructed by further deposition of calcium oxalate. Definite correction of the metabolic lesion requires liver transplantation. Mutation analysis may also be useful in taking decision whether to perform combined liver–kidney or isolated kidney transplantation in PH-I patients with ESRD. We believe that even in those PH-I patients, who already have developed ESRD, *AGXT*-mutation analysis can be very useful. It would seem advisable to perform only isolated kidney transplantation in patients homozygous for Gly170Arg or Phe152Ile. On the other hand, the adverse outcome of pyridoxine negative mutations would give a strong argument for combined liver–kidney transplantation or a timely planned liver transplantation in such patients.

## 105.6 RARE PEROXISOMAL DISORDERS

Recently, two new peroxisomal defects have been described both affecting the fission of peroxisomes. Defects affecting mitochondrial fission have already been described in literature. Indeed, mutations in the *OPA1* gene which codes for a mitochondrial dynamin-related guanosine triphosphatase have been associated with an autosomal dominant form of optic atrophy resulting in early-onset blindness (71,72). The first peroxisomal fission defect was described by Waterham et al. (73) and is an apparently autosomal dominant disease resulting from mutations in the *DLP1*-gene, which codes for dynamin-like-protein-1 (DLP1). The single patient identified with this defect so far, had microcephaly, abnormal brain gyration, optic atrophy, hypotonia, absence of any developmental milestones, and persistent lactic acidemia, which suggested a mitochondrial defect. However, plasma VLCFAs were also abnormal albeit mildly. Immunocytochemical studies in fibroblasts from the patient revealed clear abnormalities in the morphology of both mitochondria and peroxisomes, which ultimately led to the identification of DLP1 as the dysfunctional protein. The fact that DLP1 is known to be involved in both mitochondrial and peroxisomal fission explains the combination of mitochondrial (elevated lactate) and peroxisomal (elevated VLCFAs) abnormalities.

The other patient is a 25-year-old mentally retarded male who showed normal early development with walking at the age of 18 months, except from bilateral

congenital cataracts, which prompted cataract extraction at 4 months of age. At the age of 5 years a hearing problem was noted and this progressed to severe bilateral perceptive hearing loss. From the age of 10 years, he started to complain of painful muscles and showed a gradual loss of muscle strength. At the age of 12 years he was referred for extensive clinical and laboratory evaluation. Main features on neurological examination were nystagmus with a rotary component, normal muscle strength, low reflexes and normal sensibility in the arms, but low muscle strength, absent reflexes and disturbed sensibility in the legs. From the age of 15 years he had regular attacks of migraines and convulsions, was encephalopathic, complained of nausea and headache, had trouble with his vision and had a numb-feeling in his mouth and hands. These attacks often followed upon physical or mental exertion. The fact that VLCFAs had been abnormal although only once, prompted a detailed study in fibroblasts, which revealed clear abnormalities, showing elongated peroxisomes arranged in rows, indicative of a defect in peroxisome division. Subsequent studies ultimately led to the discovery of *PEX11 beta* as the mutated gene. *PEX11 beta* is known to be involved in peroxisome fission. Molecular analysis revealed homozygosity for a nonsense mutation (c.64C → T (p.Q22X)) in the *PEX11 beta* gene (74).

The identification of these two patients with atypical phenotypes resulting from defects in peroxisome fission may point to the existence of a new class of peroxisomal patients yet to be identified in detail.

In summary, much has been learned about the group of PDs in recent years. This includes the development of sensitive laboratory methods allowing the measurement of the panel of peroxisomal metabolites and follow-up enzymatic methods to pinpoint the underlying defect. Furthermore, the molecular basis of most—if not all—of the peroxisomal diseases identified so far has been resolved with obvious consequences for diagnosis, including prenatal diagnosis. The availability of these sophisticated and sensitive methods together with the rapid development of genetic techniques including whole exome and genome sequencing, has allowed the identification of atypical phenotypes including isolated cerebellar ataxia, a.o., which holds great promises for the future in terms of patient recognition. This is especially important since therapeutic measures will surely become available in the next years to come, surely for the milder variants.

### Biography

**Ronald J A Wanders** studied chemistry (subspecialization: Clinical chemistry and Biochemistry) and performed his PhD in the section Medical Enzymology and Metabolism, E C Slater Institute for Biochemical Research (supervisor: Prof Joseph Tager) and studied the flux control of metabolic pathways with emphasis on mitochondrial oxidation phosphorylation, ammonia genesis and ammonia utilization (urea cycle). In 1983, he joined the Laboratory Genetic Metabolic Diseases, Departments of Paediatrics and Clinical Chemistry, Medical Faculty, University of Amsterdam as postdoctorate with the specific task to (1) setup a laboratory for the enzymatic diagnosis of patients suspected to suffer from certain inborn errors of metabolism (IEM) and (2) start a research project on peroxisomes aimed to develop post- and prenatal diagnostic laboratory methods for ZS and identify new PDs. He was appointed as a professor in 1996, and Head of the laboratory in 2003, which is a world-renowned expert center for the laboratory diagnosis of PDs and other IEMs. The author has also set up diagnostic and research activities in the field of mitochondrial FA oxidation, cholesterol biosynthesis, cardiolipin metabolism, amino acid degradation, a.o. The author has published >965 peer-reviewed papers, including book chapters and has received multiple awards including the International Federation of Clinical Chemistry (IFCC) Distinguished Award for Laboratory Medicine and Patient Care 2011.

### 106.1 THE NATURE OF PERSONALITY

One of the most salient features of human behavior is its diversity. Some individuals are shy and reserved while others are outgoing and loquacious. Some relish the adrenaline rush that accompanies jumping out of airplanes while others are content to experience their thrills vicariously by watching reality TV. Personality is one of psychology's core constructs, posited to account for both the marked differences in behavior that exist among individuals as well as the coherence of any given individual's behavior over time and context. In short, personality psychologists believe that personality is one of the reasons we behave consistently differently from one another.

Although there are many alternative theoretical conceptualizations of personality (1), most of the empirical, and indeed virtually all of the genetic, work in this area has been based on a trait conceptualization of personality. The existence of literally thousands of trait descriptors in the English language (happy, sullen, vibrant, impulsive, withdrawn, aggressive) appears to make trait approaches unwieldy, even if it is an indication that the general public has found trait terms to be a useful way to describe human behavior (2). There is, however, a growing consensus among personality psychologists that a large portion, although certainly not all, of the variation in human behavior reflected by these trait terms can be captured by a relatively small number of core dimensions. Although there remains debate over the exact number of core personality dimensions (e.g. 3, 5, 7 or 9), currently a model that posits five is in ascendance. The Five Factor Model (FFM) of personality emphasizes five major dimensions of personality that appear to be cross-cultural universals (3): extraversion (the tendency to be positively and actively engaged in one's social and work environments), neuroticism (the tendency to experience negative moods states and psychological distress), agreeableness (the tendency to be friendly, warm and cooperative),

conscientiousness (the tendency to be planful and conform to social norms), and openness (the tendency to welcome diverse intellectual, cultural, and artistic experience) (Table 106-1). Importantly, the ability to reliably and validly assess these dimensions through self-report questionnaire has made large-scale behavioral genetic studies of personality feasible.

Much of the latter half of the twentieth century saw a decline in personality research within psychology, largely over concern personality had limited utility for helping to explain differences in our behavior. Within the past 20 years, however, there has been a surge of research implicating personality in a broad array of important life outcomes. Differences in personality predict differences in physical health (4) and how long we live (5). It is an important predictor of academic and social achievement (6) as well as performance on the job (7). It helps explain differences in the quality of our relationships with romantic partners, relatives and friends (8) and even the likelihood we get married (9) or divorced (10). Indeed, personality is as strong a predictor of important life outcomes as other major behavioral or social predictors including cognitive ability and social class (11).

Nothing has done more to revive interest in personality within psychology and psychiatry than the demonstration of its link to mental health. Personality factors are associated with risk of mental disorder ranging from depression and anxiety (12) to attention deficit hyperactivity disorder (ADHD) (13) and substance abuse (14). Significantly, these associations appear to be established early in life as personality ratings of toddlers have been shown to be predictive of mental health problems in adulthood (15). Moreover, personality may be an essential component, rather than merely a predictor, of those mental health problems that represent the extreme of quantitative variation rather than a discrete clinical entity. For example, depression has been hypothesized to be the consequence of high levels of neuroticism coupled with low levels of

extraversion (16), while many acknowledge that ADHD likely represents the extreme of a continuum of impulsivity, inattention, and overactivity (17). Resolving the genetic basis of personality will be key to resolving the genetic basis of some mental disorders.

## 106.2 TWIN AND ADOPTION STUDIES

### 106.2.1 Twin Studies

The major evidence in support of a heritable basis to personality comes from the comparison of the similarity of reared-together monozygotic (MZ) and dizygotic (DZ) twins. Analysis of twin data is based on a biometric model first introduced by the population geneticist Falconer (18). If we assume that: (1) MZ twins are no more likely than DZ twins to share trait-relevant environmental influences, (2) there is no assortative mating for personality, and (3) all relevant genetic effects are additive, then the expected correlation for reared-together MZ ( $r_{\text{MZT}}$ ) and DZ ( $r_{\text{DZT}}$ ) twins along with the total trait variance (normed to 1.0) can be expressed as:

$$\begin{aligned} r_{\text{MZT}} &= a^2 + c^2 \\ r_{\text{DZT}} &= 1/2a^2 + c^2 \\ 1.0 &= a^2 + c^2 + e^2 \end{aligned}$$

where  $a^2$  is the proportion of trait variance associated with additive genetic factors (i.e. the additive heritability),  $c^2$  is the proportion associated with shared environmental factors (i.e. those environmental factors that are shared by reared-together relatives and thus contribute to their phenotypic similarity), and  $e^2$  is the proportion associated with non-shared environmental factors (i.e. those environmental factors that are not shared by reared-together relatives and thus contribute to their phenotypic dissimilarity). Simple algebraic manipulation of these equations produces the familiar Falconer estimators of the three variance components (variously called the Falconer or ACE model):

$$a^2 = 2(r_{\text{MZT}} - r_{\text{DZT}})$$

$$c^2 = 2r_{\text{DZT}} - r_{\text{MZT}}$$

$$e^2 = 1.0 - r_{\text{MZT}}$$

Table 106-2 summarizes a meta-analysis of twin studies of the Big Five personality factors published by Bouchard (19). Three general observations, all of which have been confirmed in virtually every large-scale study of reared-together twins, can be drawn from the data presented in the table. First, additive genetic factors are estimated to account for roughly 40–60% of the variance in personality. Second, shared environmental influences on personality appear to be negligible. Finally, non-shared environmental effects are substantial and account for approximately 50% of the variance in personality. Importantly, research subsequent to Bouchard's meta-analysis confirms the robust nature of his findings across country (20), assessment modality (20b,21), and age (22).

There is thus little doubt that reared-together MZ twins are more similar in personality than reared-together DZ twins. But, does this consistent observation necessarily implicate the existence of genetic influences on individual differences in personality? The validity of the MZ–DZ comparison rests on two fundamental assumptions: (1) that the personalities of twins do not differ from those of non-twins and (2) that MZ twins are no more likely than DZ twins to share trait-relevant environmental influences. While the psychological uniqueness of being a twin has been a subject of much speculation, the empirical evidence on this issue is overwhelmingly consistent.

**TABLE 106-1 The Big Five Model of Personality**

Personality Characteristics	Characteristics of	
	High Scores	Low Scores
Extraversion	Assertive, energetic, sociable	Quiet, shy, withdrawn
Neuroticism	Anxious, emotional, moody	Calm, at ease, unemotional
Conscientiousness	Dependable, organized, practical	Careless, irresponsible, frivolous
Agreeableness	Cooperative, generous, warm	Cold, quarrelsome, selfish
Openness	Curious, imaginative, insightful	Shallow and simple

**TABLE 106-2 Mean Twin Correlations and Falconer Estimates from a Meta-Analysis of Twin Studies of the Big Five Personality Traits**

Personality Dimension	No. of Studies	$r_{\text{MZT}}$	$r_{\text{DZT}}$	Falconer Estimates		
				$a^2$	$c^2$	$e^2$
Extraversion	30	0.52	0.25	0.54	−0.02	0.48
Neuroticism	23	0.51	0.22	0.58	−0.07	0.49
Conscientiousness	12	0.44	0.24	0.40	0.04	0.60
Agreeableness	6	0.49	0.23	0.52	−0.03	0.51
Openness	7	0.43	0.17	0.52	−0.09	0.57

Note:  $r_{\text{MZT}}$  is mean correlation for reared-together MZ twins,  $r_{\text{DZT}}$  is mean for reared-together DZ twins,  $a^2$  is proportion of variance attributable to additive genetic effects,  $c^2$  is the proportion of variance attributable to shared environmental effects, and  $e^2$  is the proportion of variance attributable to nonshared environmental effects. Table is adopted from material given in Bouchard (19).

There is no evidence that the personalities of twins differ systematically from that of singletons (23), supporting the generalizability of findings from twin studies to the larger non-twin population. The second, or so-called equal environmental similarity, assumption is the basis for the inference that if MZ twins are phenotypically more similar than DZ twins it is because of their greater genetic, and not environmental, similarity. This latter assumption has received substantial attention in the empirical literature, with the consistent finding that greater MZ than DZ similarity in personality cannot be attributed to differential treatment (e.g. by parents) or exposure (e.g. rearing neighborhood) (24).

The strongest evidence against the hypothesis that differential environmental similarity can account for reared-together MZ–DZ differences in personality similarity is studies on reared-apart twins. Although few in number, studies of reared-apart twins support the three general findings from studies of reared-together twins. Table 106-3 provides a summary of the four studies that have compared the similarity of reared-together and reared-apart MZ twins on self-report measures of extraversion and neuroticism (25). MZ twins who are reared apart nonetheless show substantial similarity in personality, a finding that underscores the importance of genetic factors given that these correlations cannot be accounted for by placement effects (26). Except for the Swedish study, reared-apart MZ twins are about as similar in personality as reared-together MZ twins, further suggesting that common rearing does not have a profound impact on personality similarity. Finally, the consistent observation of MZ correlations that are substantially less than unity indicates that non-shared environmental factors are a major source of individual differences in personality.

### 106.2.2 Adoption Studies, Family Studies and Nonadditive Genetic Influences

Adoption studies have consistently found little or no personality similarity among adoptive relatives, confirming that growing up in the same home has little impact on personality similarity. Using data reported in Loehlin (27), we computed the weighted-average adoptive sibling (i.e. nonbiologically related siblings who are reared together) correlation for the five basic dimensions of personality. These average correlations are 0.07 for

measures of extraversion (three studies, total  $N$  of 258), 0.11 for measures of neuroticism (three studies, total  $N$  of 258), 0.06 for measures of agreeableness (two studies, total  $N$  of 250), 0.02 for measures of conscientiousness (two studies, total  $N$  of 245), and 0.06 for measures of openness (two studies, total  $N$  of 241). Similarly, there is little personality resemblance between adoptive parents and the nongenetically related offspring they rear.

It is informative to compare the personality resemblance of adoptive relatives not with that for twins but rather with that for first-degree biological relatives. In a longitudinal study of over 200 adoptive and 200 non-adoptive families, for example, Plomin et al. (28) reported an average, across four personality measures obtained at five different ages, adoptive sibling correlation of only 0.01. The comparable correlation in a separate sample of biological siblings was only 0.05. Moreover, the average adoptive parent-adopted child personality correlation of 0.03 actually exceeded, albeit by a trivial amount, the average biological parent-adopted child personality correlation of 0.01 in this study. Thus, first-degree biological relatives appear to show little more similarity in personality than adoptive relatives.

The consistent observation of low sibling and parent-offspring personality resemblance necessarily implies that growing up in the same home has little impact on measured personality; it suggests that the genetic factors shared by parents with their children or among siblings may also have little influence on personality similarity. This finding appears to be at odds with the consistent observation of strong heritable effects in twin studies of personality. That is, an estimated narrow-sense heritability of 50% from twin studies would imply a correlation of 0.25 among first-degree biological relatives. In fact, as suggested by the Plomin study, personality correlations among first-degree biological relatives are characteristically much lower than 0.25. For example, in a large twin family study of neuroticism, Finkel and McGue (29) reported biological sibling correlations of 0.07–0.14 and parent-offspring correlations of 0.12–0.19, less than half of the corresponding MZ correlations of 0.42–0.49. Furthermore, in a study of neuroticism that included over 45,000 individuals (30), the average biological same-sex sibling correlation of 0.14 ( $N = 10,400$ ) was less than half the corresponding same-sex MZ twin correlation of 0.40 ( $N = 4628$  pairs). Family studies thus suggest

**TABLE 106-3** Reared-Together (MZT) and Reared-Apart (MZA) Monozygotic Twin Correlations for Extraversion and Neuroticism

Study	Country	Extraversion		Neuroticism	
		$r_{\text{MZT}}$ ( $N$ )	$r_{\text{MZA}}$ ( $N$ )	$r_{\text{MZT}}$ ( $N$ )	$r_{\text{MZA}}$ ( $N$ )
Shields (25c)	Great Britain	0.42 (43)	0.61 (42)	0.38 (43)	0.53 (42)
Langinvainio (25a)	Finland	0.33 (47)	0.38 (30)	0.32 (47)	0.25 (30)
Pedersen (25b)	Sweden	0.54 (150)	0.30 (95)	0.41 (151)	0.25 (95)
Tellegen (25d)	USA	0.63 (217)	0.34 (44)	0.54 (217)	0.61 (44)

a narrow-sense heritability of personality on the order of 20–30% (i.e. twice the first-degree relative correlation) rather than the 40–60% typically reported in twin studies.

Although there are several possible explanations for the discrepancy in heritability estimates from studies of twins and nuclear families, including biases in the twin method or age moderation of personality similarity (i.e. twins share an age while other biological relative pairings do not), the explanation that has the greatest empirical support is the existence of nonadditive genetic effects. Specifically, because MZ twins share all their genetic material, interactions between alleles at a single locus (genetic dominance) or among alleles at multiple loci (epistasis) will contribute to their phenotypic similarity. Because first-degree relatives, however, are not likely to share all the components in an interactive genetic system identical by descent, nonadditive genetic effects likely contribute minimally to their phenotypic similarity.

Combined biometric analysis of twin and non-twin family data support this conclusion. Finkel and McGue (29) reported that nonadditive genetic effects accounted for from 7% to 24% of the variance in measures of extraversion, from 3% to 36% of the variance in measures of neuroticism, and from 13% to 45% of the variance in measures of conscientiousness. Interactive genetic effects were also estimated to account for from 10% to 13% of the variance in neuroticism in Lake et al.'s (30) massive twin family study, from 5% to 45% of the variance in various personality measures in a unique study of biological and adoptive families (31), and for 12% of the variance in impulsivity based on a recent meta-analysis of twin, family and adoption studies (32). The existence of nonadditive genetic effects has implications far beyond accounting for discrepancies in heritability estimates. Most investigations aimed at identifying the specific genes affecting personality are based on a single-locus paradigm. That is, the effect of each genetic locus is assessed singly, independent of genetic variation at other loci. If there are significant nonadditive genetic effects, then the effect of one locus will depend on genotype status at one or more other loci. Researchers may risk failing to identify important genetic effects on personality unless they take a multi-locus approach.

### 106.2.3 Twin and Adoption Studies of Personality and the Nature of Environmental Influence

One of the most remarkable findings to emerge from twin and family studies of personality concerns the nature of environmental rather than genetic influence. Both studies of personality similarity among adoptive relatives and the comparison of personality similarity among reared-together versus reared-apart twins suggest that growing up in the same home has very little effect on personality. These findings stand in stark contrast

to models of personality development that dominated within psychology throughout most of the twentieth century and that emphasized the primary role of parents in shaping their children's personalities (33). But while behavioral genetic research has led to a re-evaluation of the nature of environmental influence, it has not led to a rejection of the existence of those influences. The personalities of MZ twins correlate only about 0.50, implying that fully half of the variance in personality can be attributed to environmental factors, albeit environmental factors that create differences rather than similarities among reared-together relatives. The unexpected nature of environmental influence implied by behavioral genetic research has resulted in a large research effort aimed at identifying specific non-shared environmental influences on personality (34) and a debate over whether these influences owe to idiosyncratic stochastic processes (35), epigenetic phenomenon (36), or systematic psychological processes (37). It remains to be seen whether this new perspective will finally allow researchers to determine the circumstances by which some people end up gregarious, adventurous, or compliant.

### 106.2.4 Summary of Twin and Adoption Studies of Personality

Twin and adoption studies have consistently implicated the importance of both genetic and environmental factors in the etiology of individual differences in normal-range variation in personality. Heritability estimates from studies of reared-together twins suggest that approximately 50% of the variance in personality is associated with genetic factors, with some significant portion of these heritable effects likely to be due to non-additive gene action. The heritable basis of personality provides justification for molecular genetic studies aimed at identifying the specific genes influencing personality. However, the complexity of the personality phenotype suggests that multiple genes are involved, and they will be difficult to identify if they interact in their effect on personality as is suggested by twin and adoption studies. Behavioral genetic research also suggests that the major source of environmental influence on personality may be due to factors that create differences rather than similarities among reared-together relatives. What these non-shared environmental factors are and how they combine with genetic factors to influence personality remain to be determined.

## 106.3 THE SEARCH FOR GENES THAT INFLUENCE PERSONALITY

### 106.3.1 Candidate Gene Approaches

Throughout the last decade of the twentieth and the early part of the twenty-first century, research aimed at identifying the specific genetic factors that underlie

the heritability of personality was dominated by the candidate gene approach. Several factors contributed to this focus. First, the biological basis of differences in personality had been hypothesized to be due to differences in brain neurotransmission systems, with different systems thought to underlie the different dimensions of personality. So, for example, the neurotransmitter dopamine had been implicated in brain reward and approach systems (38), making polymorphisms in the dopaminergic system a convenient target for study of personality traits such as impulsivity and sensation seeking. Alternatively, the serotonin system is known to be involved in emotion regulation (39) and pharmacologic interventions for depression and anxiety target the reuptake of serotonin into the presynaptic neuron by the serotonin transporter (5-HTT). Consequently, genetic variation in the serotonin system has been the target of candidate gene studies of neuroticism and anxiety-related personality characteristics. Second, relatively early on geneticists had identified markers, many of which were functional or in coding regions, for several key genes in the relevant neurotransmitter systems. Thus, a variable number of tandem repeat (VNTR) marker in the third exon of the gene that codes for the dopamine D4 receptor (*DRD4*) (40) has been the focus of a large number of behavioral studies as has a functional insertion/deletion polymorphism in the promoter region of the gene that codes for 5-HTT (gene label is *SLC6A4*, polymorphism is 5-HTTLPR) (41).

The year 1996 was a watershed for research on the genetics of personality. Over the span of just a few months, two of the most prestigious scientific journals in the world, *Nature Genetics* and *Science*, published separate research studies that each purported to have found a major gene variant associated with normal-range differences in personality. The January issue of *Nature Genetics* provided two independent reports of an association between the *DRD4* VNTR polymorphism and personality measures of novelty seeking (42), providing what appeared to be compelling confirmation of an influential hypothesis advanced by Cloninger et al. (43) that genetic variation in the dopamine system would be relevant to novelty seeking. In November of that same year, *Science* featured a report by Lesch et al. (44) associating a polymorphism in *SLC6A4* with neuroticism in two

independent samples. Particularly impressive was the amount of variance accounted for by these variants. The *DRD4* variant was estimated to account for 5% of the phenotypic and 10% of the genetic variance in novelty seeking; the 5-HTT polymorphism accounted for 3–4% of the phenotypic and 7–9% of the genetic variation in neuroticism. With specific genetic effects of this magnitude, there was considerable optimism that the genetic architecture of key personality dimensions would soon be resolved (45).

These initial publications were followed by a perplexing pattern of successful and failed attempts at replication. The failure to observe consistent replication was not, however, specific to personality. Failure to replicate initial genetic association results was characteristic of candidate gene association studies with a broad range of behavioral and nonbehavioral phenotypes (46). The factors that contributed to this poor record of replication are now fairly well understood. Initial candidate gene studies was substantially underpowered, designed to detect effects that were an order of magnitude larger than the magnitude we now know to be typical of the effects of specific genetic variants on complex phenotypes. An underpowered study is more likely to produce a false-positive finding with an overestimated effect size than a true-positive finding, a phenomenon geneticists have called the “winner’s curse” (47). The problem of candidate gene studies was further exacerbated by their focus on single genetic variants in each of a small number of relevant genes (i.e. the “usual suspects”), whose selection was driven as much by what polymorphisms could be genotyped as by strong theory as to which genetic systems were relevant.

In an attempt to circumvent the problems inherent to small sample studies, geneticists have increasingly turned to meta-analysis (48). Table 106-4 provides a summary of major meta-analyses of candidate gene studies of personality-related phenotypes published since 2008. Several features of the table warrant comment. First, several of the genetic variants that have been the focus of considerable personality research do not show significant meta-analytic effects. This is most notable for the *DRD4* VNTR polymorphism, which has been extensively investigated but for which there is little

**TABLE 106-4 Findings from Major Meta-analyses of Candidate Gene Studies of Personality-Related Phenotypes Published Since 2008**

Study	Gene	Polymorphism	No. of Samples	Personality Characteristics	<i>d</i> ( <i>p</i> -value)
Munafo (82)	<i>DRD4</i>	Exon 3 VNTR	36	Approach-related scales	0.04 ( <i>p</i> = 0.14)
		C521T	11	Approach-related scales	0.25 ( <i>p</i> < 0.001)
Munafo (83)	<i>SLC6A4</i>	5-HTTLPR	28	Harm avoidance	0.02 ( <i>p</i> = 0.37)
			28	Neuroticism	0.07 ( <i>p</i> = 0.001)
Munafo (60)	<i>SLC6A4</i>	5-HTTLPR	14	Amygdala activation	0.63 ( <i>p</i> < 0.001)
Frustaci (84)	<i>BDNF</i>	Val66Met	4	Neuroticism	0.24 ( <i>p</i> < 0.05)
			5	Harm avoidance	0.11 ( <i>p</i> > 0.05)

*d* gives the meta-analyzed standardized mean personality difference between the genotype.

evidence of an association with approach-related traits such as impulsivity and sensation seeking. Second, even in cases where the pooled effect is significant, the magnitude of the effect is modest. This is most notable for the 5-HTTLPR polymorphism, which is significantly associated with neuroticism but with a pooled effect size of less than 0.1 standard deviations. Finally, for amygdala activation in response to the presentation of emotional stimuli the effect size is sizable ( $d=0.63$ ), suggesting that nearly 10% of the variation in this phenotype is accounted for by the polymorphism. The phenotype in this case is, however, a measure of brain function underlying personality rather than a self-report measure of personality.

### 106.3.2 Genome-Wide Strategies

The limited success of candidate gene studies of personality has motivated alternative approaches that do not depend on strong hypotheses about the probable locus of genetic effects. There have been eight published genome-wide linkage studies of personality-related traits (49). Most of these studies involve neuroticism because it is the personality factor most strongly implicated as a risk factor for mental health problems. While these studies have reported suggestive linkage findings for several chromosomal regions, none of these regions has received consistent support and no confirmed associations between variants in these regions and personality have emerged as a result of the linkage findings. As is well known, one of the limitations of the linkage approach is that it is underpowered to detect variants other than those that have relatively large phenotypic effects (50). The failure of linkage to identify genetic variants associated with personality is likely a consequence of the small effects associated with these variants.

The recent development of efficient methods for high-throughput genotyping has made feasible what geneticists had only speculated about previously—the ability to comprehensively evaluate the association of complex phenotypes with common genetic variation throughout the whole genome. A genome-wide association study (GWAS) involves genotyping large numbers of individuals on several hundreds of thousands or even millions of genetic markers and then determining whether variation in each of these markers is associated with the target phenotype. Each marker is a known and common (greater than 5% of a population has the rarer allele) single-nucleotide polymorphism (SNP or single base pair change) selected so that in aggregate the entire genome is densely covered (a GWAS typically includes at least 500,000 SNPs). Association is estimated with a linear regression of the phenotype on each SNP (along with various covariates), with the  $p$ -value threshold set to  $p < 5 \times 10^{-8}$  to account for the multiple testing burden. Because of the density of coverage across the genome, this method can find important variants with much

smaller effects than those that can be detected with linkage analysis. Due to linkage disequilibrium (the probability that two SNPs that are located physically near on another will be inherited together), the interpretation of a significant association is not that the marker itself is causal but rather that it is close to the causal variant.

Only recently have personality researchers turned to GWAS. The first personality GWAS examined only neuroticism (51) but there soon followed a study of all Big Five traits (52) as well as a study of temperament (53). The most highly associated SNPs in these studies failed to meet the stringent significance threshold of  $p < 5 \times 10^{-8}$ , but several were marginally significant. Of these nominally significant SNPs, several showed some evidence of replication in the replication samples included in the original GWAS. Furthermore, many reside in or near genes involved somehow in the central nervous system and may be of interest in further studies. For example, a SNP in the gene *SNP25* on chromosome 20, associated with neuroticism traits (52), is known to be important in neurotransmitter release, axon growth, and synaptic plasticity. It is important to note, however, that over half of all genes are expressed in the brain, so these genes may still be dead ends.

Findings with other phenotypes, including those that are non-behavioral as well as behavioral, suggest the reason why GWAS have failed to provide conclusive evidence of SNP associations with personality. Specifically the magnitude of phenotypic effect associated with any specific genetic variant is likely to be small, accounting for less, and likely much less, than 0.5% of phenotypic variance. Because the initial round of personality GWAS had sample sizes around a few thousand individuals, however, they were substantially underpowered to detect associations of this magnitude. For example, a sample of 4000 unrelated individuals would have power of less than 20% to detect effects as large as 0.5% of variance. To remedy this problem, a meta-analysis of GWAS personality data from several research groups was recently carried out (54). After combining several datasets from Caucasian populations worldwide, researchers ended up with a sample of over 17,000 individuals. With this number of participants, power exceeds 80% to detect effect sizes of 0.25% or more. This meta-analysis provided evidence for genetic loci associated with two personality dimensions: a region near the gene *RASA1* with openness to experience and the *KATNAL2* gene and conscientiousness. Each locus explained about 0.25% of variance in the associated trait. *RASA1* produces a protein involved in intracellular signaling and cellular proliferation and differentiation and is expressed moderately in the brain. *KATNAL2* produces a protein that may be involved in neuronal migration, axonal growth, and dendritic pruning.

Although these findings are exciting, we cannot yet have confidence that they are true associations because neither finding remained significant in the analysis of the replication sample. Again, researchers are left to wonder if effect sizes are even smaller than a quarter of a percent,

requiring even larger sample sizes to detect them, or if rare SNPs or other kinds of genetic variation (e.g. large deletions) are responsible for personality variation. If the latter is true, genome sequencing may be a promising approach to finding important variants. Alternatively, it may be, as twin and adoption research suggests, that genetic effects on personality are nonadditive, in which case the standard one SNP at a time approach to analyzing GWAS data is known to be inefficient.

## 106.4 STRATEGIES TO INCREASE THE SENSITIVITY OF GENETIC STUDIES OF PERSONALITY

### 106.4.1 Genetic Scores

Given the small effect associated with any specific individual genetic variant, one strategy to increase the sensitivity of genetic analysis involves creating genetic scores that capture the aggregate effect of multiple variants. For example, in a sample of approximately 4000 adults, McCrae et al. (55) created aggregate genetic scores for each of the Big Five factors by summing SNPs that were associated with each factor at different  $p$ -value thresholds. The cross-validated correlations of these scores in an independent replication sample ranged from a nonsignificant 0.009 for extraversion to a significant 0.125 for openness. Although the cross-validated correlations are modest, these results suggest that there are individual signals being genotyped that should, in principle, be detectable in sufficiently large samples. Similarly, Chen et al. (56) showed that an aggregate score reflecting genetic variation in the dopamine system was significantly associated with a measure of highly sensitive personality. The development and validation of genetic scores hold great potential for better understanding the molecular basis of personality.

### 106.4.2 The Endophenotype Approach

Personality characteristics are clearly far removed from the primary function of DNA, so that any genetic effects on personality must be mediated by the multiple biological, physiological, and neurological systems that are intermediate between primary gene product and observed behavior. Gottesman and Gould (57) have argued that resolving the genetics of complex phenotypes such as personality may best be achieved indirectly, by first resolving the genetics of relevant intermediate or endophenotypes. For example, it may be conjectured that the effect of specific genetic variants may be stronger, and thus easier to identify, for endophenotypes than for observed behavior because the former are more proximal to the primary gene product than the latter. Consistent with this hypothesis, Ducci and Goldman (58) have shown that the magnitude of the effects of candidate polymorphisms on various endophenotypes is substantially greater than for phenotypic disease.

Although only at the initial stages of inquiry, promising findings are already emerging from endophenotype research on personality. Developments in imaging technology have allowed neuroscientists to learn much about the neurological basis of individual differences in personality (59), providing a rich source of potential endophenotypes. As noted above, genetic variation in 5-HTT appears to be relatively strongly associated with the processing of emotionally laden stimuli in the amygdala (60), while a recent meta-analysis reported a strong effect of a functional genetic variant in the gene coding for the enzyme catechol-O-methyltransferase (COMT, involved in the degradation of catecholamines) on activation of the prefrontal cortex (61). Similarly, functional polymorphisms in other dopamine or serotonin system genes have been associated with measures of brain function that have been implicated in trait anxiety and impulsivity (59b). The combination of genetic and neuroimaging approaches holds great potential for unraveling the genetics of complex behavioral systems like personality (62).

### 106.4.3 Animal Models

As any pet owner will know, animals, like people, have personalities. Indeed, there is considerable evidence that the five factors of personality seen in humans also emerge in behavioral ratings of individuals representing a wide range of different species (63). As with human personality, much of the individual differences in animal personality factors appears to be moderately to strongly heritable (64), suggesting that genetic variants affecting personality in humans might effectively be identified using animal models. Consistent with this proposition, genetic variation in DRD4, which we previously showed was related to approach-related personality factors in humans, has been associated with exploratory behavior in an avian species (65).

One of the most promising animal models for a complex behavioral system is the open-field model of emotionality in the mouse. When placed in a novel, brightly illuminated open field, mice display various levels of fear, which can be objectively quantified in terms of motor activity, wall-seeking behavior, and defecation. These behavioral indicators have been pharmacologically validated as measures of anxiety and are substantially heritable and evidence the nonadditive genetic effects characteristic of human personality (66). Flint et al. (67) reported a quantitative trait locus (QTL) analysis of emotionality in the F2 intercross progeny from parental lines selected for high or low open-field activity. Three QTL (murine chromosomes 1, 12 and 15) gave consistent evidence of linkage across four separate measures of emotionality. Each QTL accounted for from 3% to 9% of the trait variance. In a study of open-field behavior in the F2 progeny of A/J and C57BL/6J mice, Gershenfeld et al. (68) independently replicated the finding of QTL for emotionality on chromosomes 1 and 15.

Moreover, genetic analyses of intercrosses from C3H/HeJ by C57BL/6J (69) and C57BL/6J by DBA/2J (70) revealed a QTL on chromosome 1 that influenced fear conditioning in the mouse.

Taken in aggregate, the strongest evidence for a QTL affecting murine emotionality is on chromosome 1, although additional regions have emerged in subsequent research (71). High resolution mapping of the relevant region of chromosome 1 suggests, however, that there are likely multiple loci in this region affecting different aspects of open-field emotionality (72). Importantly, these regions are syntenic to regions on human chromosome 1q that have been implicated in linkage studies of neuroticism (73). Although no known candidate genes have as yet been identified in the replicated QTL regions, these findings clearly provide encouraging support for the existence of genes affecting emotionality in man and mouse.

### 106.5 GENE-ENVIRONMENT INTERPLAY AND THE DEVELOPMENT OF PERSONALITY

In evaluating genetic research on human personality, it is essential to recognize the fundamental differences that exist between human behavior and other heritable human phenotypes. First, environments are not distributed at random but rather are a reflection in part of an individual's own behavior. An easygoing, affable individual will experience a much different social environment than a tense, surly individual. It is highly unlikely that these experiential differences, which emerge early and can endure throughout development, are without psychological effect. Consistent with this perspective, research on twins indicates that individuals high in neuroticism are more likely to experience psychological adversity than individuals low in this personality trait (74), while individuals low in conscientiousness are more likely to place themselves in high-risk situations (75). The resulting "genetic" correlations between neuroticism and life stress or conscientiousness and risk taking raise the possibility that some of what is labeled as heritable effects on personality may actually reflect a complex interplay between genetic factors and the psychological environments our personalities help us create.

Second, genetic effects on personality are almost certain to depend on environmental exposure. The notion that gene-environment interactions play a fundamental role in the development of behavior gained widespread acceptance within psychology following two highly influential publications. The first was the finding that the 5-HTTLPR short allele increased risk of depression only when the individual is exposed to a stressful environment (76); the second was the observation that a functional polymorphism in the MAO-A gene is associated with increased risk of aggressive behavior only when a

child has a history of abuse (77). It would be hard to overstate the impact these two studies have had within psychology; the rate of publication of papers on gene-environment interaction and behavior went from being irregular to more than one per day (78). Despite the popularity of the approach, there is growing concern that gene-environment interaction research suffers from the same difficulty with replication that has plagued candidate gene association studies in psychology. The original interaction involving the 5-HTTLPR polymorphism has not held up in rigorous meta-analysis of relevant studies (79), and it appears that most interaction studies are substantially underpowered and thus likely to produce false-positive results (80). While there is little doubt that gene-environment interaction effects on behavior and personality are pervasive, reliable detection of these effects will likely require methodologically stronger research (81).

### 106.6 CONCLUSION

Genetic research on personality is at a transition. Early twin and adoption studies documented the importance of genetic influences and showed that the major source of environmental influence lies outside the family. The major goal of genetic analysis is now to identify the specific genes that influence individual differences in personality and determine how the effects of those genes interact with and are modulated by experience. As with any complex phenotype, we can expect that progress in mapping genes for personality will be slow and subject to false leads. Nonetheless, research in this area holds great promise in not only bringing about a better understanding of mental health but also in illuminating the biological basis of human nature.

## Fragile X Syndrome and X-linked Intellectual Disability

*Kathryn B Garber, Stephen T Warren, and Jeannie Visootsak*

Department of Human Genetics, Emory University School of Medicine, Atlanta, GA, USA

This article is a revision of the previous edition article by Grant R Sutherland, Jozef Gécz and John C Mulley, volume 3, pp 2523–2547, © 2007, Elsevier Ltd.

### 107.1 OVERVIEW

Intellectual disability (ID) is a broad diagnostic category with a variety of underlying etiologies that include both environmental and genetic factors. “Intellectual disability” is replacing “mental retardation” as the preferred term, although they refer to the same impairment (1). A plethora of genes participates in the development of the human brain, and disruption of many of these processes can impede normal intellectual development. With the development of comparative genomic hybridization arrays, which fostered our ability to detect submicroscopic changes to chromosomes, structural chromosome aberrations have been observed in an increasing number of individuals with ID that had previously gone without an underlying cause (2). Although these defects have been found across the genome, the fact remains that the X chromosome has an overabundance of known ID genes. This is at least partly responsible for the finding by various epidemiological studies that there is ~1.4-fold excess of males affected with ID compared to females (3–5). Because males have a single X chromosome, they are more sensitive to mutations that reduce the expression or activity of genes encoded therein. Females, on the other hand, have a second X chromosome that, for many genes, can provide compensatory activity for the mutated gene/genes. However, with the advent of next generation DNA sequencing, autosomal recessive loci resulting in ID will be uncovered. While each locus is likely to be individually rare, the aggregate of autosomal loci will likely dwarf the number X-linked causes in the future.

X-linked ID (XLID) is estimated to account for 10–12% of ID cases in males (6). The most common form of XLID, and the first group that could be split from the heterogeneous nonsyndromic XLID (NS-XLID)

category, was fragile X syndrome (FXS). Mutations in many different X-linked genes have since been identified in individuals with both syndromic and nonsyndromic forms of XLID, although, individually, each of these genes accounts for a small fraction of ID overall. Despite the advances made in XLID research, the underlying etiology remains unclear in a significant proportion of families with probable XLID (6,7), and NS-XLID remains a viable diagnostic category. In this chapter, we will summarize what is broadly known about the genes that contribute to XLID with particular emphasis on the FXS.

### 107.2 FRAGILE X SYNDROME

With an estimated 1 in 4000 males affected, FXS is the most common inherited form of ID (8). ID and behavioral abnormalities are central to the phenotype. Approximately 85% males and 25–30% females with FXS will have an intelligence quotient (IQ) below 70, which falls in the ID range. The associated cognitive deficits also impact executive function, visuospatial-processing abilities, attention, and working memory. Although originally considered to be a nonsyndromic form of ID because its associated physical characteristics are relatively subtle, a more distinct syndromic picture is now apparent (Figure 107-1). Affected males tend to have a long narrow face, prominent ears, and joint hypermobility; macroorchidism is present from puberty (9). Individuals with FXS generally do not have significant medical issues. Recurrent otitis media and recurrent sinusitis may be present during childhood (10). Gastroesophageal reflux is also common during infancy and early childhood, and symptoms may include irritability and colic. The frequency of seizures in FXS is ~13–18 % in boys and ~5% in girls. The risk of seizures will be

**FIGURE 107-1** Two males affected with FXS. The boy on the left is 10 years of age, and the man on the right is 26 years old. One of the few recognizable facial features associated with FXS is prominent ears, which are notable on this child but less so on the older individual.

higher in childhood, with peak incidence between 6 months and 4 years, with mean age of onset of 2 years (11,12). Different types of seizures have been reported in FXS, with the most common type being complex partial seizures.

Behavioral and psychological issues are prominent and wide-ranging in individuals with FXS. The behavioral phenotype includes shyness, social avoidance, anxiety, hyperarousal to sensory stimuli, autistic behavior (e.g. hand flapping, poor eye contact, perseverative-behavior or speech), hyperactivity, impulsivity, inattention, self-injurious behavior, aggression, and mood instability (13–16). These features are typically grouped into the following symptom clusters: (1) Attention Deficit/Hyperactivity Disorder (ADHD)-like symptoms of hyperactivity, distractibility, impulsivity, and overarousal; (2) anxiety-related symptoms, including obsessive-compulsive disorder (OCD)-like and perseverative-behaviors; (3) emotional lability; and (4) aggressive and self-aggressive behavior (17).

FXS is the most common single gene cause of autism, resulting in 2–6% of all cases of autism (18). Based on the Autism Diagnostic Observation Scale and the Autism Diagnostic Interview, ~30% of males with FXS have autism spectrum disorder (ASD), and another 20–30% have pervasive developmental disorder, not otherwise specified (15,19). Even those children with FXS who do not meet the criteria for ASD diagnosis usually have one or more autistic characteristics, such as hand flapping, poor eye contact, repetitive behaviors and language, and tactile defensiveness. Individuals with FXS and comorbid ASD are more severely impacted by social impairment and lower cognitive functioning and adaptive behavior compared to those with FXS without ASD (20,21).

Females with FXS typically have milder behavioral and cognitive problems than males with FXS because they have one normal copy of the relevant gene. Approximately 25% of females with FXS have

an IQ <70; the remaining have a high propensity for learning and/or behavioral issues including depression, withdrawal, social anxiety, and executive dysfunction (22).

### 107.2.1 Diagnosis

FXS is typically not suspected in infants unless there is a family history of FXS and/or ID. The syndrome includes no distinct physical features at birth to prompt the diagnosis, and the physical features that do develop are often subtle prior to puberty and may become more apparent with increasing age (10). Macroorchidism generally begins to present after 8 years of age with testicles being 2–3 times normal in mid-adolescence (9). Typically, the presenting concerns for a child with FXS are developmental delays and/or behavioral problems. These delays can be evident in gross motor, fine motor, and/or language skills (23). The behavioral problems include autistic-like behaviors such as hand flapping, poor eye contact, and social deficits. Due to the overlap of FXS with more common forms of ID and autism and to the prevalence of FXS, it is recommended that genetic testing for FXS be offered for all children with developmental delay and/or autism.

A 2003 study conducted with 274 FXS families indicated that the typical diagnosis of FXS occurred at approximately 32 months of age, an average of 18 months after the family first identified concerns (24). Despite efforts to increase FXS awareness in the medical community through patient advocacy, professional recommendations regarding prompt diagnosis, and increased exposure to information about FXS in the pediatric literature, no change was detected in the age of diagnosis of FXS when this study was repeated in 2009 with 1250 additional families (25). The average age of FXS diagnosis remained relatively stable across the 7-year period at ~35–37 months.

### 107.2.2 Molecular Genetics

In the vast majority of cases, FXS is caused by a CGG trinucleotide expansion in the 5' untranslated region of *FMR1*. This leads to hypermethylation and transcriptional silencing of the gene, which normally encodes the fragile X mental retardation protein, FMRP. Expanded *FMR1* alleles arise from meiotic instability of the so-called premutation alleles, which have higher number of repeated units than those found in the general population. In other words, premutation alleles can change in size when they are passed from one generation to the next and when the allele expands greatly in size, the *FMR1* gene is shut off. The mechanism of this repeat instability is unclear.

There are four allelic classes for the *FMR1* trinucleotide repeats, and these categories are based on the observations of allele instability in affected families (Table 107-1). They are normal alleles, which range in size up to 40 copies; intermediate alleles, which range in size from 45–54 repeats and may exhibit some slight instability but are otherwise considered normal alleles; premutation alleles, which can expand to a full mutation and range from 55–200 repeats; and full mutations, which are >200 repeats in length and are hypermethylated (26,27). Although premutations can change to full mutations in a multistep (i.e. multigeneration) process, this allele class was defined by the smallest premutation allele that has been observed to expand to a full mutation in a single generation, which was 59 repeat units in size (28). The 55 repeat unit cutoff for the definition of premutation alleles reflects the fact that there is some laboratory-to-laboratory-based variability in allele sizing (26).

Intermediate-sized *FMR1* alleles are significantly less stable than are the normal alleles; in a large screen of mother–child pairs in the French Canadian population, 7% of the intermediate-sized alleles changed in size when transmitted from the mother to child, compared to 1% of normal transmitted alleles (27). Three out of four intermediate alleles that did change between generations increased or decreased by a single repeat unit (27). However, it is important to note that expansions of intermediate alleles to full mutations within two generations have been reported (29,30). A similar study by

Nolin et al. (31) found that 9% of maternal alleles sized 45–49 repeats were unstable when transmitted, but this fraction increased to 26% in larger intermediate-sized alleles of 50–54 repeats (Table 107-2). Of the unstable transmissions of intermediate alleles in the Nolin et al. study, 50% increased by one repeat unit, and 89% changed by ≤4 repeat units. In one case, an increase of 31 repeat units (from 54 to 85 units) was observed, and this resulted in the expansion of an intermediate allele into the premutation class.

Premutation alleles of *FMR1* are unmethylated alleles that are transcribed and translated. Relative to normal alleles, they produce increased *FMR1* transcript levels, and in general, slightly lower levels of FMRP (32,33). Alleles of this size can expand incrementally during meiosis to produce a slightly larger premutation allele. When passed from females, they can also undergo massive expansion into the full mutation range in a single generation. This expansion is restricted to females because full mutations cannot be maintained during spermatogenesis (34). In fact, full mutations are only rarely found in the sperm of FXS males; premutations are present instead (35). No differences are found in the stability of premutations based on the sex of the offspring (27,31).

The likelihood that a premutation will expand to a full mutation is governed by the size of the premutation allele, as illustrated in Figure 107-2 and Table 107-2, and by the presence of AGG interruptions to the CGG-repeat sequence. The longer the length of the 3' pure CGG repeat tract, the less stable the premutation allele (36). Conflicting data exist on the likelihood of premutation expansion based on family history of FXS. Levesque et al. (27) did not observe differences in premutation instability between families with a history of FXS compared to premutation carriers from the general population. On the other hand, Nolin et al. found that the likelihood of a premutation expanding to a full mutation was correlated with prior family history and suggested that this may be due to interfamilial differences in the pattern of AGG interruptions in the transmitted allele (31).

Although the length of the CGG repeat in *FMR1* determines its stability, the size of a full mutation does not determine the severity of FXS (37). In females with a full mutation in *FMR1*, the biggest determinant of the severity of the phenotype is X inactivation. In these females, the phenotype can range from normal intellectual abilities to full FXS (37), and the larger the active fraction of full mutation-carrying chromosomes in these females, the more severe will be the phenotype. In males with a full mutation, the methylation status of the mutation can influence the severity of the phenotype. Although complete methylation of the full mutation is the norm, some individuals exhibit methylation mosaicism, meaning that the full mutation is not methylated in all cells. Another type of mosaicism that can be observed in males with FXS is mutational mosaicism. In this situation, some

**TABLE 107-1** The Allele Classes of *FMR1* and Their Phenotypic Consequences

Category	Repeat Size	Consequence
Normal	≤45	—
Intermediate	45–54	No established clinical significance
Premutation	55–200	Risk of FXS in next generation(s) Primary ovarian insufficiency Fragile X Tremor–Ataxia syndrome
Full mutation	>200	Fragile X syndrome

**TABLE 107-2 The Instability of Maternal Repeats Increases with Size**

Maternal Repeat Size	Fetal Outcome			
	Smaller than Full Mutation			Full Mutation (%)
	Unstable Transmissions (%)	Average Increase in Repeat Size	Average Decrease in Repeat Size	
45–49	5/55 (9)	1.0	0	0
50–54	13/51 (26)	5.1	8.7	0
55–59	37/86 (43)	5.9	2	0
60–69	60/79 (76)	13.2	12.3	2/81 (2)
70–79	32/33 (97)	22.4	20.5	15/47 (32)
80–89	16/16 (100)	29.3	18.2	45/61 (74)
90–99	0/1 (0)			31/33 (94)
100–200	2/2 (100)		68.0	93/95 (98)

Data derived from Nolin et al. *Prenatal Diagnosis* 2011, 10, 925–931. Fragile X Analysis of 1112 Prenatal Samples from 1991 to 2010.

**FIGURE 107-2** Risk of full mutation in offspring increases with maternal repeat size. Maternally transmitted intermediate-sized alleles (blue shading) do not increase to full mutations in one generation. The likelihood of transmitting a full mutation dramatically increases with the size of a maternal premutation (green shading).

cells in the body contain a premutation and others a full mutation allele that is hypermethylated and silenced. Both forms of mosaicism are correlated with increased IQ scores, presumably due to the fact that some FMRP is expressed in these individuals (38,39).

### 107.2.3 Cytogenetics

The term FXS describes the X-chromosome fragile site that is detectable cytogenetically when a full mutation is present in *FMR1*. The underlying mutational mechanism was not understood when this was first described, so observations of the fragile X chromosome were the first diagnostic test used for FXS. Peripheral lymphocytes must be grown under conditions of thymidylate stress for the fragile site to be observed, and it is seen only in a fraction of cells from an affected individual, so this was a less-than-optimal diagnostic approach. The cytogenetic approach also does not detect premutation alleles, which prevented accurate risk assessment in affected families.

It should be noted that the fragile site that can be documented in individuals with FXS is not the sole fragile site on the X chromosome. The FXS fragile site has been dubbed as FRAXA and is located at Xq27.3. Nearby at Xq27.2 is FRAXD, which is a common fragile site and has been confused with FRAXA in cytogenetic analyses, although it has no known pathologic significance (40). There are two more rare fragile sites at Xq28 that each result from expansion of trinucleotide repeat tracts. The FRAXF fragile site contains a gene called *FAM11A*, but has not been definitively correlated with a particular phenotype (40). Within the FRAXE fragile site, on the other hand, is the *FMR2* gene (also known as *AFF2*), which contains a CCG triplet repeat that expands in a fashion similar to that of the *FMR1* CGG repeat. This expansion has been described in individuals with a form of NS-XLID (41) but it is much more rare than FXS (42). Similar to FMRP, the product of *FMR2* is an RNA-binding protein that binds to G-quartet structures. It is believed to participate in the

regulation of RNA transcription and alternative RNA splicing (43–45).

### 107.2.4 Inheritance

FXS is inherited as an X-linked dominant trait with reduced penetrance, but the mutational mechanism for this disorder gives rise to a characteristic inheritance pattern in families. Typically, intellectually normal males pass the relevant allele on the X chromosome to an unaffected daughter, who then passes the allele to an affected son. Due to the instability of premutation alleles as they are passed from generation to generation, and to the fact that larger premutation alleles are more likely to expand to a full mutation (28), the likelihood that FXS will be penetrant in a family increases down through the generations. This provides the resolution for the so-called Sherman paradox, which was the finding that, in FXS families, the mothers of transmitting sons were less likely to have sons with FXS than were daughters of transmitting males.

### 107.2.5 Premutation Phenotypes

Individuals who carry a premutation allele at *FMR1* do not have FXS, but they are at risk of having other *FMR1*-related disorders. The best documented of these are fragile X-associated tremor/ataxia syndrome (FXTAS) and fragile X-related primary ovarian insufficiency/premature ovarian failure (FXPOI). Premutation carrier females may also be at increased risk for depression and anxiety, and late-onset neurological issues including hypothyroidism, fibromyalgia, and neuropathy (46,47), but these associations are not always confirmed once covariates are taken into account (48,49). While FXS is due to the lack of FMRP, the premutation-associated disorders result from the accumulation of CGG-repeat containing *FMR1* transcripts (50). This idea is supported by the fact that no RNA or protein is produced from *FMR1* full mutations, but there is an excess of *FMR1* transcript and a deficiency of FMRP associated with premutations (32,33). Further, individuals with FXS do not exhibit features of FXTAS nor FXPOI, suggesting they occur by a different mechanism.

FXTAS includes intention tremors, gait ataxia, cognitive decline and dementia, balance problems, and peripheral neuropathy (51). These symptoms may progressively worsen over time (52). Women with FXPOI have decreased ovarian reserve, irregular menstrual periods, hormone fluctuations, and increased risk for premature ovarian failure (menopause before the age of 40) (53). Both phenotypes exhibit age-dependent penetrance, and overall, the penetrance and severity of symptoms is correlated with the size of the premutation allele (53,54). This correlation is not linear for FXPOI; instead the highest risk of premature ovarian failure is found in the middle of the premutation

range and could be due to the excess FMRP production associated with alleles of this size (55). This hypothesis is supported by the identification of a family that carries a duplication encompassing *FMR1* in which all carrier females experienced premature ovarian failure (56).

The mean age of onset for FXTAS is in the early 60s (57), and nearly 50% of 70–79-year-old men who carry a premutation allele have features of FXTAS (58). Fewer female premutation carriers have FXTAS. In a study by Rodriguez-Revenga et al. (59), 16.5% of female premutation allele carriers had signs of FXTAS by age 50, compared with 45.5% of males. Although a larger fraction of women might have features of FXPOI, the penetrance of fragile X-related premature ovarian failure—which is the most extreme end of FXPOI—is 1% by age 18 and 15–24% by age 40 (53).

### 107.2.6 Genetic Testing

Genetic testing for FXS and for *FMR1* premutations involves an assessment of the size and methylation status of the CGG repeat tract in the 5' UTR of *FMR1*. A polymerase chain reaction with primers that flank the repeat tract is used to size the repeat, and the product is visualized by capillary gel electrophoresis. A Southern blot is used to determine the methylation status of the repeat, as well as to estimate the size of full mutations that are too long to be amplified by PCR. This approach will detect the vast majority of cases of FXS. It is believed that approximately 1% of cases of FXS are due to point mutations or full/partial deletions in *FMR1* (60), but a more accurate assessment of this prevalence is unavailable because *FMR1* sequencing is rarely performed. Although a limited number of *FMR1* mutations have been reported in boys who presumed to have FXS, it is not clear whether, in general, point mutations in *FMR1* will yield the same phenotype. Sequence analysis of *FMR1* in 50 boys with an FXS-like phenotype yielded one deletion in *FMR1*, but no other pathogenic sequence changes (61). A larger study of 963 boys with developmental delay identified one potentially pathogenic missense change in *FMR1* (62). Despite this low frequency of sequence mutations, *FMR1* sequence analysis can be considered in males with a clinical picture consistent with FXS in whom the *FMR1* CGG repeat tract is normal.

Due to the fairly high prevalence of FXS and the subtlety of the syndromic features, it is recommended that genetic testing for FXS be included as a first-line genetic test for all individuals with developmental delays, learning issues, ID and/or ASD (60). This is estimated to have a diagnostic yield of ~1–2% (63). Females with a history of infertility should also be screened for premutations in *FMR1*. A family history of movement disorders, early menopause, learning disabilities, ID, or autism should increase the suspicion for FXS (64).

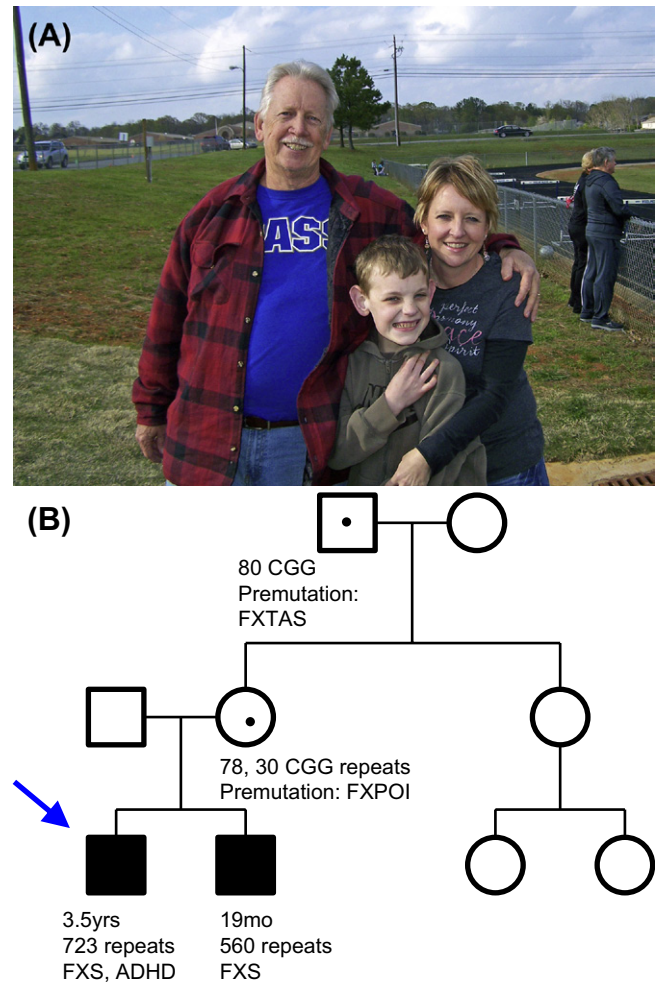

### 107.2.7 Genetic Counseling

Genetic counseling and cascade testing should be recommended upon the identification of FXS in a family with the aim of identifying both premutation carriers and individuals with FXS (64). FXS is often termed “a family of disorders” because there is a wide spectrum of involvement, both medical and psychiatric, in a single family (9), as illustrated in Figure 107-3. This means that early diagnosis has important implications not only for the child with FXS, but also for the immediate and extended family members.

Premutation carriers should be counseled as to their risks of having a child with FXS and to their own risks of developing FXTAS and/or FXPOI. As the cascade testing strategy is planned, particular attention should be paid to certain aspects of the extended family history, including whether and which individuals have ID, behavioral or learning issues, infertility or premature menopause, tremor, ataxia, or other neurological disorders, and psychiatric issues, such as cognitive decline, depression, dementia, or anxiety (64). This is particularly important due to recent evidence that the risk of passing a full mutation to a child is lower for premutation carriers with no family history of FXS (31).

One of the difficult issues that arise in counseling families for *FMR1*-related disorders is the identification of a CGG repeat tract that falls in the intermediate class of 45–54 repeats. Although no alleles in this size range have been reported to expand directly to a full mutation, and these alleles are generally considered to be stable, meiotic instability is significantly higher than is observed for alleles in the normal range (27), particularly in the 50–54 repeat range (31), so careful counseling of these families is warranted (37). Intermediate alleles have been observed to expand to full mutations in two generations (29,30).

Other than use of repeat size, it is difficult to predict which premutation carriers will suffer from FXPOI or FXTAS. There are limited data that hint that magnetic resonance imaging (MRI) studies may detect changes in prefrontal activity and reductions in gray matter in the anterior subregion of the cerebellar vermis in premutation carriers, even when they have not been diagnosed with FXTAS (65,66). It remains to be seen whether this turns out to be a predictor of FXTAS in premutation carriers. Predictions of ovarian dysfunction in premutation carriers have focused on hormone levels. Increased levels of follicle-stimulating hormone and decreased levels of inhibin B, inhibin A, and progesterone at certain times of the menstrual cycle have been recorded in female premutation carriers, even when they have regular menstrual cycles, and this is believed to be indicative of early ovarian aging (53,67,68). Anti-Müllerian hormone is reduced in premutation carriers with repeat sizes  $\geq 70$ , relative to those with shorter premutation alleles, and may better

**FIGURE 107-3** The family of Fragile X disorders. (A) A three-generation family affected by *FMR1*-related disorders. The boy on the right has FXS and an *FMR1* full mutation, which he inherited from his mother, who has FXPOI due to an *FMR1* premutation; her father has FXTAS due to the premutation. (B) Pedigree of the family at identification. The proband was a 3 ½-year-old boy with FXS. His 19-month-old brother also has FXS. The diagnoses and *FMR1* repeat allele sizes are indicated underneath each relevant individual.

predict early ovarian decline than the other hormones (69), but definitive assays for predicting FXPOI have not yet been developed.

The potential for preimplantation genetic diagnosis for FXS should be a component of the discussion with premutation carriers who are interested in having children. The effects of the premutation on reproduction, as described above, are relevant in this discussion. The potential for premature ovarian insufficiency may shorten the reproductive window in these women. In addition, ovarian stimulation for oocyte retrieval is more difficult in *FMR1* premutation carriers, and they may need more gonadotrophins for this stimulation than women without a premutation allele (70,71). The failure rate for ovarian stimulation is higher for women with a premutation allele (13%) than those without (~1%), but, of note, the majority of premutation carriers who

are completely refractory to ovarian stimulation have regular menstrual cycles (71).

### 107.2.8 Epidemiology

Approximately 1:5000–1:4000 males have FXS, and this frequency is lower in females, due to the reduced penetrance of the full FXS phenotype (72–74). A large, anonymous screen of samples for *FMR1* premutations (of which 99% were females) estimated that 1:178 females and 1:400 males in the general population is a premutation carrier (75). Based on previous penetrance estimates, these data were used to calculate that the prevalence for FXTAS in males is 1:4848 and for FXPOI in females is 1:3560 (75).

### 107.2.9 Screening

Traditional population screening includes conditions (e.g. phenylketonuria) for which early treatment can prevent severe morbidity and mortality. More recently, newborn screening programs have expanded to include conditions that may not meet all the traditional screening criteria. No states currently screen for FXS in newborns, but it has been considered for possible inclusion in these programs. The under-recognition of FXS despite its prevalence and the increased potential of targeted pharmacological intervention provide arguments for this type of screening, but it was not until recently that this type of screening was feasible on a large scale due to technological advances in our ability to detect *FMR1* mutations.

The techniques that are used to diagnose FXS are too labor-intensive and costly to incorporate into large-scale screening programs. Several PCR-based screening techniques have been developed to get around these problems. These include methods to facilitate the amplification of long GC rich tracts (76,77), and methylation-specific PCR methods that detect methylated full mutations of *FMR1* (72). It should be noted that the *FMR1* allele classes that can be detected via a screen are determined by the technique used; some techniques can detect premutations, whereas the methylation-based methods detect only full mutations. Further, the methylation-based techniques do not detect approximately 20% of females with a full mutation, due to the presence of the second X chromosome (72). Although these techniques make population screening for *FMR1*-related disorders possible, this idea is not without controversy (78,79), including the fact that some premutation carriers might not want to know from early in life that they are at risk of an *FMR1*-related disorder in adulthood and the fact that girls with a full mutation might be stigmatized by the screen even though they may not have ID. General population screening for FXS is not currently recommended by the American College of Medical Genetics (60) or the American College of Obstetricians and Gynecologists (80).

Population screening for FXS does not necessarily have to occur in newborns; preconception screening of *FMR1* in adult women has also been debated (78,79). Preconception screening (screening for premutation carriers) assesses a woman's risk for having a child with FXS and determines the woman's risk for FXPOI. It may be less stressful for women as compared to waiting for the screening test result during the pregnancy or after the birth of a child. Additionally, women can elect alternative reproductive options such as adoption, embryo donation, egg donor, or preimplantation genetic diagnosis. With preconception screening, women will have more time to make informed decisions. Access to genetic counseling, education, and resources will be important for the successful implementation of preconception screening. It should be kept in mind that premutation carriers identified through general population screens may not have as high a risk of having a child with FXS as those identified through cascade screening of affected families (31).

It often takes a long time for FXS to be recognized and diagnosed, and families may give birth to a second child before a diagnosis is made and are thus not counseled as to relevant reproductive options for their family (24). Furthermore, this can delay diagnosis of the premutation-associated disorders, FXPOI and FXTAS, in older members of the family. Thus, research has explored the attitudes of affected families toward FXS screening. In a survey of 442 parents of children with FXS, parents indicated their support for voluntary screening for FXS, especially carrier and newborn screening (81). Approximately 93% of the surveyed parents indicated that they believe that FXS genetic testing should be offered to parents prior to conception, and 83% felt this testing should be available for newborns. Parents made arguments in support of early testing, such as the potential to obtain services for their child earlier, increased understanding of their child's needs, and the ability to make informed reproductive decisions. These parents also remarked on the potential negative outcomes of screening, which could include increased worry about their child's development and future, increased stress, insurance discrimination, and strained relations with extended family members (81). Pediatricians also support early screening of high-risk infants for cystic fibrosis, Duchenne muscular dystrophy, and FXS (82). These physicians preferred the idea of infant screening over newborn screening for FXS, and they suggested that screening be voluntary and require informed consent. Screening in later infancy allows parents make an informed decision about the test and allows time for the parents to bond with their child before a diagnosis is made. Given that most states do not require parental consent for newborn screening, but not all parents want to know this diagnosis at the birth of their child, informed consent is an issue for FXS newborn screening.

**FIGURE 107-4** The function of FMRP in the neuron and its regulation by mGluR. FMRP regulates local translation of mRNAs near synapses. mGluR stimulation at synapses has several effects on FMRP. These include: (1) Rapid activation of PP2A, which dephosphorylates FMRP, resulting in rapid depression of target mRNAs and their subsequent translation. (2) This local translation of proteins such as PSD-95, MAP1b, APP, and Arc, leads to AMPA receptor internalization. Next, and with slower kinetics after mGluR stimulation, FMRP is rephosphorylated by S6K1, bringing it back to a state of translational repression. (3) mGluR stimulation leads to FMRP ubiquitination and its proteasome-dependent degradation, which is necessary for mGluR long-term depression. (4) A retrograde signal leads to transport of new FMRP-associated mRNAs from the soma. (5) FMRP can shuttle into the nucleus. (6) We speculate that it may pick up new target RNAs there and bring them back to the synapse. (Reprinted from *Neuron* 60(2) Bassell; Warren. *Fragile X Syndrome: Loss of Local mRNA Regulation Alters Synaptic Development and Function*, 2008; pp 201–214, with permission from Elsevier.)

### 107.2.10 Mechanisms

FMRP is an messenger RNA (mRNA)-binding protein (83) that is abundantly expressed in the brain, where it is involved in RNA trafficking (84) and the regulation of local protein synthesis in dendrites (85) (see Figure 107-4). FMRP is a negative regulator of translation, and—in its phosphorylated form—is associated with stalled polyribosomes (86). In the absence of FMRP, as in FXS, translation of specific mRNAs is dysregulated, and this is associated with altered synaptic function. FMRP has been shown to bind several specific mRNAs and influence their expression (Table 107-3). Intimately tied to the function of FMRP is signaling through the group 1 metabotropic glutamate receptors, mGluR1 and mGluR5. In hippocampal neurons, activation of mGluR can trigger long-term depression, which is a long-lasting change in synaptic strength. This process requires localized translation of mRNAs that are found in postsynaptic dendrites (87) and is accompanied by long-term changes to the rate of endocytosis of AMPA receptors (88). mGluR stimulation triggers the movement of FMRP and its bound mRNAs to dendrites and the release of the FMRP-mediated

brake on mRNA translation (89). This, in turn, stimulates endocytosis of AMPA receptors. In the absence of FMRP, the lack of feedback inhibition in this system gives rise to excess basal translation of FMRP-regulated mRNAs and a lack of mGluR-stimulated local translation (90), which lead to increased AMPA receptor internalization (91) and excessive hippocampal and cerebellar long-term depression (LTD) (e.g. weakening of synaptic connections) (92). This presumably underlies the abnormal dendritic morphology, which includes an overabundance of dendritic spines with an immature morphology, and the subsequent weakening of neural connections and synaptic plasticity that are evident in humans with FXS and in *FMR1* knockout mice (90). The definition of these molecular defects in FXS has led to the development of new therapies for FXS that are currently in trial, as will be described later in this chapter.

### 107.2.11 Treatment

The current psychopharmacology treatment in FXS is symptom-based combined with supportive strategies,

TABLE 107-4 Current Psychopharmacology Treatment in FXS		
Behavioral Problems	Medication Class	Medications
Hyperactivity, Inattention, Impulsivity	Stimulants or Non-stimulants	Stimulants: Methylphenidate and Amphetamine Non-stimulants: Strattera, Intuniv
Overarousal and hypersensitivity	Alpha-agonists	Clonidine and Guafacine
Anxiety, obsessive-compulsive disorder, perseverative	Selective Serotonin Reuptake Inhibitor (SSRIs)	Fluoxetine, Fluvoxamine, Sertraline
Aggression/self-injurious	Atypical Antipsychotics	Risperidone, Aripiprazole, Olanzapine, Quetiapine, Ziprasidone, and Aripiprazole

which include speech therapy, occupational therapy, behavioral interventions, and a specialized educational program. As behavior in FXS can greatly impact academic and social functioning, medications may be necessary to decrease maladaptive behavior and/or prevent dangerous consequences of the behavior. Additionally, medications may optimize the individual's functioning and potential, and allow for integration in the educational and social environment. Medications are always combined with intervention therapies (e.g. speech therapy), behavioral strategies, and educational support and resources. An overview of the pharmacological treatments currently used to manage FXS can be found in Table 107-4 and will be detailed below.

**107.2.11.1 ADHD Treatment in FXS.** The prevalence of ADHD symptoms is more common in children with FXS than it is in individuals with other genetic conditions or individuals with nonspecific ID (93). ADHD symptoms are the most prevalent problem behavior in individuals with FXS and in male premutation carriers (16,94). Overall, 54–59% of boys with FXS meet the diagnostic behavioral criteria for either ADHD-inattentive type only, ADHD-hyperactive type only, or ADHD-combined type based on parent or teacher report (16). In addition to behavioral intervention and individualized therapies, medications must be

considered to improve symptoms of hyperactivity, inattention, and impulsivity.

Stimulants are the most frequently used class of medication in boys with FXS (17). However, data on the efficacy of stimulants in children with FXS are limited. Stimulants continue to be the first-line of treatment for intellectually typical children with ADHD, but their efficacy in children with cognitive deficits has been questionable. Stimulants are frequently not effective in children with severe ID, and an IQ <45 is associated with poor response (95,96). For FXS, stimulants improve the hyperactivity and inattention symptoms of approximately 67–75% of affected children (17,97). In a double-blind crossover trial of methylphenidate and dextroamphetamine compared to placebo, 10 of 15 (67%) prepubertal boys with FXS were noted to have improvements in attention span and socialization skills. Response rate to stimulants may be relatively lower in adult males with FXS because of higher propensity toward anxiety and decreased activity level (17). Overall, our current knowledge about the benefits of stimulants for people with FXS continues to be positive, and these medications can improve distractibility, attention span, and impulsivity in individuals with FXS.

The most commonly used stimulants for treatment of ADHD in FXS are methylphenidate (Ritalin) and

amphetamine (Dexedrine and Adderall). Short-acting stimulants may require frequent dosing, as the duration of activity is typically 2–6 h. The long-acting stimulants first became available in 2000 and are the preferred treatment for most children with FXS. They are equally effective but with fewer side effects, such as the irritability and rebound in the late afternoon that are often seen with short-acting stimulants (97). Short-acting stimulants may be used in conjunction with long-acting stimulants to decrease symptoms of ADHD at the beginning or end of the day or to manage adverse effects as medication wears off. Examples of long-acting methylphenidates are Concerta, Metadate CD, Ritalin LA, and Focalin. Daytrana is the first methylphenidate transdermal patch, which offers flexible duration of action because it is applied once daily and the medication lasts approximately 3 h after the patch is removed. Examples of long-acting amphetamines include Vyvanse, Adderall XR, and Dexedrine Spansule. Pemoline is a stimulant with associated risk of hepatotoxicity that was discontinued in 2005.

Despite being the most prevalent medication used to manage FXS, it should be kept in mind that the efficacy and side effect profiles of stimulants in individuals with FXS vary considerably. The common side effects of stimulants include decreased appetite (with or without weight loss), abdominal pain, headache, insomnia, and growth retardation. Occasionally stuttering, decreased talking, or increased seizures may be seen (17). It is important to be cautious when increasing the dose because children with FXS are sensitive to stimulants and may have exacerbated outbursts and mood lability at higher doses. The cardiovascular system is also stimulated, resulting in an increase in heart rate and blood pressure. If motor or vocal tics develop, non-stimulants such as atomoxetine and guanfacine should be considered. Children taking stimulants should be monitored for weight, height, heart rate, and blood pressure before and during treatment. Non-stimulants may be preferred in children <5 years of age, as stimulants may induce irritability and other behavioral issues in young children. These behavioral problems may not be present when stimulants are reintroduced at an older age.

The first non-stimulant approved for the treatment of ADHD is Strattera (Atomoxetine), a norepinephrine reuptake inhibitor. Strattera is an alternative option for individuals with FXS who cannot tolerate stimulants. Anecdotal reports and our experience suggest that Strattera can be helpful for females with premutations who have ADHD and anxiety. The most common side effects of Strattera are decreased appetite, abdominal pain, nausea and vomiting, somnolence, and fatigue. Intuniv is a new non-stimulant for treatment of ADHD, and studies on its use in FXS have not been published.

Clonidine (Catapres) and guanfacine (Tenex) are alpha-adrenergic agonists that were initially developed to treat hypertension in adults but have been used for

years without Food and Drug Administration (FDA) approval to treat a variety of behavioral concerns in children, including those in children with FXS. In a survey of clonidine use in 35 children with FXS, 63% of parents reported that clonidine was helpful for their child, while 20% found it a little helpful, 11% indicated behavior was worse, and 6% reported that there was no effect (98). Clonidine is prescribed to treat the hyperactivity, overstimulation, and attention/concentration problems associated with FXS. Clonidine has also been used to treat sleep disorders, a common issue in children with FXS. At low doses, clonidine can increase rapid eye movement (REM) sleep and decrease non-REM sleep, whereas at higher doses, the effect is reversed in the second 1/3 of the night (99). The most common side effect of clonidine is sedation, which is often transient and manageable by dose reduction. Blood pressure should be monitored and abrupt withdrawal avoided, due to the risk of rebound hypertension and withdrawal arrhythmias.

Guanfacine can help with ADHD symptoms, including hyperactivity and frustration tolerance (100). Guanfacine is used commonly in FXS, as it is generally less sedating than clonidine and has a longer half-life. For example, a 0.1 mg dose of clonidine is equivalent to a 1 mg dose of guanfacine. As with clonidine, abrupt withdrawal should be avoided (101).

**107.2.11.2 Anxiety Treatment in FXS.** Selective serotonin reuptake inhibitors (SSRIs) are the treatment of choice for anxiety, depression, and mood symptoms (102). In the FXS population, antidepressants, particularly SSRIs are helpful more than 50% of the time in helping with anxiety and behavioral/emotional symptoms (17,103,104). Fluoxetine (Prozac) can be effective in treating selective mutism and extreme shyness in females with FXS (105). In addition, based on a self-reported survey, fluoxetine improves anxiety, tantrums, or aggression in 70% of adults with FXS.

Pediatric research is limited on SSRIs, as not all SSRIs have been approved by the FDA for use in children. Approved SSRIs are fluoxetine (Prozac; approved for depression and OCD), fluvoxamine (Luvox; approved for OCD), and sertraline (Zoloft; approved for OCD) (102). An unblinded prospective study in 12 children with FXS revealed that sertraline showed improvement in emotional and behavioral problems based on parental questionnaires; however, response in language fluency and pragmatics were not noted (17). SSRIs are beneficial in targeting obsessive-compulsive behavior, irritability, inability to tolerate changes and transitions, and social anxiety in individuals with FXS. Higher doses of SSRIs can lead to behavioral activation, which causes increased hyperactivity and disinhibition, changes in appetite, insomnia, nausea, and decreased sexual drive or impotence (17). SSRIs cause activation in ~20% of individuals with FXS, as evidenced by symptoms of restlessness, mood changes, and disinhibited behavior (e.g. aggression) (103). Of this class, fluoxetine is associated with

more activation and may be suitable for individuals with shyness, social anxiety, or withdrawal, whereas those who tend toward hyperactivity and impulsive behavior may respond better with the less activating SSRIs. Individuals who are over-sensitive to the activating effects of SSRIs may tolerate venlafaxine (Effexor) or tricyclic antidepressants, which decrease reuptake of both serotonin and norepinephrine, thereby targeting both anxiety and attention problems (17). Careful monitoring of EKGs and anticholinergic effects (e.g. dry mouth, dry nose, blurry vision, constipation, urinary retention) must be considered when using tricyclic antidepressants. Although it has not specifically been reported in individuals with FXS, SSRIs can increase suicidal ideation in depressed patients; careful monitoring of patients for mood changes is important. Currently, the FDA has not reported any completed suicides in youths with or without FXS on SSRIs (102).

**107.2.11.3 Treatment of Aggression and Mood Instability in FXS.** Atypical antipsychotics are generally helpful for individuals with FXS who exhibit severe behaviors such as aggression, irritability, mood instability, and perseverative behavior. Despite the finding that approximately 80% of individuals with FXS respond to at least one antipsychotic medication, these drugs are less widely used in individuals with FXS than are the stimulants and SSRIs (17,106). Risperidone (Risperdal) has been the most frequently used antipsychotic medication and showed high response rates for aggressive behavior and other aberrant behaviors in older males with FXS and in young boys with FXS and autistic traits. This is consistent with the double-blind, placebo-controlled trial in individuals with autism (but not FXS), which reported that risperidone is safe and effective for aggressive and aberrant behavior (107).

Aripiprazole (Abilify) is the second most frequently used atypical antipsychotic in FXS, with response rates of ~70% (108,109). Aripiprazole targets distractibility, anxiety, mood instability, aggression, and aberrant social deficits (110). Some individuals cannot tolerate aripiprazole because its side effects are similar to stimulants and can include agitation or aggravation of aggressive, irritable, and perseverative-behaviors (108).

In general, the side effects of atypical antipsychotics include sedation, nausea, constipation, extrapyramidal reactions, impaired coordination, gynecomastia, and weight gain (17). Tardive dyskinesia appears to be extremely rare in individuals with FXS on prolonged treatment with antipsychotics. Risks of diabetes, fatty liver, or metabolic syndrome may be increased in general populations treated with these drugs (17). There is no information available on these risks in the FXS population, although monitoring for these conditions with periodic glucose in fasting condition and liver function studies are necessary, especially for individuals experiencing rapid weight gain. The newer atypical antipsychotics (risperidone, olanzapine, quetiapine, ziprasidone,

and aripiprazole) are less sedating than older medications (haloperidol and thioridazine). Certain atypical antipsychotics (quetiapine, ziprasidone, aripiprazole) have less effect on weight and were helpful for aggressive behavior in some patients with excessive weight gain on risperidone or olanzapine (108).

#### **107.2.11.4 Future Pharmacotherapies for FXS.**

Although current therapies for FXS are aimed at symptom management, the future of psychopharmacology treatment in FXS is promising, as it is specifically directed at preventing and/or improving some of the cognitive and behavioral features in FXS. The enhanced mGluR5-dependent hippocampal and cerebellar LTD, exaggerated synaptic weakening, and increased internalization of AMPA receptors associated with loss of FMRP, as described above, are believed to underlie the cognitive deficits in FXS (89). Thus, therapeutic strategies that incorporate mGluR5 antagonists might reduce excess mGluR5-mediated dendritic translation and its downstream effects and thus be useful in treating some of the symptoms of FXS (111). Selective mGluR5 antagonists, including the prototype of the class, 2-methyl-6-(phenylethynyl)pyridine (MPEP) has been studied in animal models of FXS (112). It rescues hyperactivity and audiogenic seizures in knockout mice, and cognitive and neuroanatomical phenotypes in a *Drosophila* fruit fly model of FXS (113).

Clinical trials in individuals with FXS are currently being conducted with several compounds that target the mGluR5 pathway. Fenobam, a high potency and selective mGluR5 antagonist, is comparable to MPEP (114). Fenobam was previously investigated as an anxiolytic in several phase II studies in the early 1980s with reported central nervous system-related side effects including hallucinations, vertigo, paraesthesias, and insomnia, especially in higher doses (115). In a pilot open-label, single-dose trial of Fenobam in 12 adults with FXS, no significant adverse events were identified (116). Decreases in hyperactivity and anxiety were reported, and improvement of the prepulse inhibition was seen in 50% of the subjects. Phase I and II clinical studies in FXS are presently underway for several other mGluR5 antagonists: R04917523 (Roche, Basel, Switzerland), AFQ056 (Novartis, Basel, Switzerland), and STX107 (Seaside Therapeutics, Boston, MA). In a double-blind, crossover study of AFQ056 in 30 males with FXS, aged 18–35 years, adverse events were reported by 80% of the subjects, mostly fatigue and headache. No significant effects were noted between AFQ056 and placebo groups in the Aberrant Behavior Checklist scores. However, the study data suggested that the response in AFQ056 treatment might be predicted by the methylation status of the *FMR1* promoter. Seven subjects with full methylation showed significant effects of AFQ056 treatment in the ABC and Repetitive Behavior Scale, whereas, subjects with partial methylation did not show any significant improvements with AFQ056 treatment when compared to placebo (117).

Lithium is an alternative strategy to target the excessive signaling through the mGluR pathway and may potentially correct the overactive dendritic protein synthesis in FXS (118). Lithium reduces mGluR-activated translation and reverses phenotypes in the *Drosophila* FXS fly model and *FMR1* knockout mouse. In an open-label trial of lithium in 15 males with FXS (6–23 years of age), improvements in behavioral functioning, adaptive skills, and verbal memory were reported (119). Results were not as positive for the Ampakine compound CX516. This class of compounds facilitates the activity of AMPA receptors, thereby targeting a downstream effect of excess mGluR activity. A Phase II double-blind, placebo-controlled clinical trial evaluating the safety and efficacy of CX516 in individuals with FXS found no significant improvement in memory, language, attention/executive function, behavior, and overall functioning in CX516-treated subjects compared to placebo (120).

Targeting the GABA system may provide an alternative treatment strategy in FXS. GABA is a key inhibitory neurotransmitter system in the brain and works in opposition to the excitatory glutamate pathways. The expression of various subunits of the GABA-A receptor is reduced in knockout FXS mice and in *Drosophila* *dFMR1* knockout flies (121). This appears to render these organisms more sensitive to excess glutamate signaling and may be responsible for the observation that high levels of glutamate in food are lethal to *dFMR1*-deficient flies (122). This lethality provided the impetus for a screen of 2000 compounds to identify those that rescue this glutamate-induced lethality and lead to the identification of three that implicate the GABA inhibitory pathway as a counter-effect to the lethality. One of these was the GABA-B agonist baclofen. Baclofen has since been found to ameliorate the abnormal phenotypes in several animal models of FXS, including audiogenic seizures and hyperactivity in the FXS mice (123). In both human and animal studies, arbaclofen, which is the active isomer of racemic baclofen, appears better-tolerated and more efficacious than racemic baclofen. Studies are now being conducted to explore the efficacy, safety, and tolerability of arbaclofen, STX209, (Seaside Therapeutics, Boston, MA) in adolescents and adults with FXS.

Minocycline, a tetracycline antibiotic, inhibits the activity of matrix metallo-proteinase-9 (MMP-9), which is elevated in the hippocampus of *FMR1* knockout mice and may be partially responsible for the immature dendritic spine profile of hippocampal neurons (124). In an open-label, add-on trial of 20 adults with FXS (13–32 years of age), behavioral improvements were noted (125). Two subjects sero-converted to a positive antinuclear antibody test, which is suggestive of a lupus-like reaction likely induced by the drug. Additionally, minocycline can cause graying of teeth in children younger than 7 years of age if their permanent teeth have not erupted. Of note, with long-term use minocycline can cause graying of other tissues and increased sensitivity to sunlight.

It is hoped that the targeting of therapeutics to ameliorate the underlying pathophysiologic mechanism of FXS will result in improved outcomes for affected individuals. Many FXS clinical trials are currently underway and we await the results with eagerness. These medications could perhaps also be effective in the treatment of more common forms of autism or other neurodevelopmental disorders, which may overlap FXS in terms of the underlying molecular mechanisms.

### 107.3 OTHER FORMS OF XLID

Because ID is a heterogeneous grouping of disorders, the underlying etiology can be difficult to uncover. Several factors have made the X chromosome a research focus for genetic causes of ID, including the significant excess of males affected with ID, the relative simplicity of genetic analysis in males because they have a single X chromosome, and the fact that many of the genes encoded on the X chromosome are expressed in the brain. Nearly 100 of the more than 800 annotated protein-coding genes on the X chromosome have been implicated in XLID (Table 107-5) and there are estimated to be as many as yet-unidentified putative XLID genes. These XLID genes have been compiled by the Greenwood Genetics Center (<http://www.ggc.org/xlmr.htm>) and at the International Workshop on Fragile X and X-linked mental retardation (<http://xlmr.interfree.it/home.htm>). Other than *FMR1*, which is estimated to account for approximately 25–40% of XLID (126,127), and *ARX*, which was found to be mutated in 7.5% of XLID families (6), each accounts for only a small fraction of cases of XLID, meaning that there are many target genes when genetic testing for XLID is considered.

#### 107.3.1 Diagnosis

It is estimated that approximately 10% of ID in males is due to genetic defects on the X chromosome (127), including the FXS. A thorough evaluation must be undertaken before XLID is considered as a likely diagnosis, and a diagnosis of XLID is typically made in males once other causes of ID have been excluded (42). Consensus guidelines from the American Academy of Pediatrics, the American College of Medical Genetics, the American Academy of Neurology, and others suggest that the evaluation of a child with developmental delay or ID should include: a three-generation pedigree, a thorough clinical history, including pre- and perinatal history, and physical and neurological examinations that include particular examinations for minor anomalies or neurologic signs that may suggest a particular diagnosis (128–130). Environmental contributions to ID, particularly lead and prenatal alcohol exposure, must also be considered. A recommended first tier of laboratory testing for developmental delay includes fragile X testing and chromosomal microarray analysis (whole genome array-comparative genomic hybridization—array CGH), which has

This information was compiled from OMIM, the Greenwood Genetics Center, and the International Workshop on Fragile X and X-linked Mental Retardation.

supplanted karyotyping in the cytogenetic analysis of individuals with developmental delay due to its increased diagnostic yield (2). Provided no diagnosis is achieved following this evaluation, the family history must be evaluated, with particular attention to individuals with learning problems, autism, psychiatric problems, or ID itself because they could share an underlying genetic etiology and could suggest a diagnosis. Although in classic XLID pedigrees, one would expect multiple affected males who are related through unaffected females, it may not be possible to document an extensive family history in every family, nor are the families always large enough to observe this pattern. Thus, XLID should be considered in males with ID of unknown etiology, and it should not be ruled out in females with ID.

Traditionally, XLID has been broken into two categories: syndromic and nonsyndromic. NS-XLID includes those families in which ID is the only consistent clinical feature, although it is clear that syndromic XLID is under-recognized by clinicians, in part because the additional phenotypic features can be subtle and because they may not be readily apparent at young age. As described below, the lines between these categories often blur as the genes for XLID are defined and as groups of patients with ID due to mutations in the same gene are compared. For the most part, we will approach this discussion from a gene-based standpoint because of the problems with categorization. However, although these categories are somewhat artificial, careful examination for the physical features that might suggest one of the syndromic forms of XLID is the only way to systematically direct molecular

diagnosis of XLID. In the absence of such clinical clues, the XLID genes can be ordered for molecular diagnostics based on what is known about the frequency of mutation in a population. However, as sequencing technologies have improved and as the costs of large-scale sequencing have gone down, there is now the possibility of sequencing all, or at least many, potential XLID genes in a diagnostic setting at one time.

### 107.3.2 XLID in Females

The focus tends to be on affected boys when we think of XLID, but XLID can also manifest in females. For some conditions, such as FXS, males are more likely to be affected than females, and the phenotype tends to be less severe in females that are affected, due to the presence of a wild-type copy of the ID gene on the second X chromosome in females. For other conditions, such as Rett syndrome, the majority of affected individuals are female. It was once believed that mutations in *MECP2* were not compatible with life in males. A variety of mutations in *MECP2* have now been described in males. The most common phenotype in males is a severe phenotype of neonatal-onset encephalopathy with microcephaly, but they can also have nonsyndromic ID (131). The classic Rett phenotype is still largely restricted to females (132).

### 107.3.3 Nomenclature

NS-XLID families are given sequential MRX numbers that are coordinated through the Human Genome

Organization Nomenclature Committee (<http://www.genenames.org/>). Genetic linkage to the X chromosome must be established before an MRX number is assigned. These numbers are withdrawn as the relevant mutations are identified in these families, and the families are reassigned a relevant gene name. Because these numbers are family-based, sometimes multiple families share an underlying mutated gene.

### 107.3.4 Gene Discovery

Large consortia have been at the forefront of gene discovery in XLID. Two key consortia in this endeavor are the International Genetics of Learning Disabilities Consortium (GOLD; <http://goldstudy.cimr.cam.ac.uk/>) and the EuroMRX cohort consortium ([www.euomrx.com](http://www.euomrx.com)). Both have collected large samples of families with probable XLID that were prescreened for FXS and cytogenetic abnormalities. An inheritance pattern consistent with XLID is a key aspect of the inclusion criteria for both consortia, necessitating multiple affected males in each family. Each group has performed extensive molecular and cytogenetic analyses in an attempt to find the underlying genetic abnormality in each family. In the EuroMRX cohort, putative X chromosome mutations have been identified in 12% of the families, and this fraction increases to over 40% in families with stronger evidence of X-linkage (6). Members of the GOLD consortium sequenced the coding exons of 718 X-chromosome genes in probands from each of 208 families with probable XLID (7). The sequence data generated from this analysis has revealed several new XLID genes.

### 107.3.5 Copy Number Variation

Sequence variation is not the only pathogenic variation responsible for ID; pathogenic copy number variants (CNVs) on the X chromosome are also quite common. Comparison of GOLD probands indicates that, in general, the ID is more severe in cases with pathogenic structural variation compared to those with pathogenic sequence variation or to those with an unknown cause (133). There is an excess of pathogenic duplications on the X chromosome, perhaps because deletions are lethal in males, who are hemizygous for the X chromosome (134). This excess could also be partially due to the relative ease of array CGH-based detection of X-chromosome duplications in males, compared to the detection of duplications on autosomes (134).

Using high-resolution array CGH, pathogenic CNVs on the X chromosome are found in approximately 5% of cases of ID in males (134,135). Pathogenic CNVs have so far been detected in 10% of the GOLD consortium families that have been analyzed. This includes 3.6% with *MECP2* duplications and 1.6% with duplications that include *HUWE1* and *HSD1710B* (133). However, it should be noted that these numbers could be inflated

because some of the GOLD consortium samples were specifically included in the Whibley et al. study due to the fact that they were already known to have a known pathogenic CNV. However, *HUWE1-HSD17B10* duplications have been reported by others and appear to occur in patients with nonsyndromic ID (136). Other studies have confirmed that—in males with ID—duplications at Xq28 that include *MECP2* are one of the most common sources of pathogenic CNV on the X chromosome. These are estimated to occur in ~1% of cases of unexplained ID in males (137). The *MECP2* duplication phenotype will be described further below.

### 107.3.6 Genetic Testing

CNV on the X chromosome should be detected in whole genome array CGH, which is part of the recommended first tier of testing in individuals with ID. The likelihood of finding a causative CNV on the X chromosome is increased when the affected male comes from a large family with demonstrated XLID, although these changes are also found in sporadic cases (135). They are also more common in syndromic ID compared to nonsyndromic ID (135).

Due to the large number of XLID genes and the lack of a defined phenotype associated with many of them, sequence-based testing for XLID has not been used widely in the genetic evaluation of ID, but this is likely to be increasingly common as we gain a more complete understanding of the XLID genes and as DNA sequencing costs decrease. For example, Emory Genetics Lab offers sequencing of more than 90 genes in a panel-based format designed for clinical testing of XLID. In a clinical diagnostic setting, one must keep in mind that the likelihood of finding a pathogenic sequence change or CNV will be lower than described by the GOLD and MRX consortia, because the inclusion criteria for these consortia increase the likelihood of a causative genetic change on the X chromosome. A broader group of idiopathic ID patients, as would be expected in a clinical setting, would include both X-linked and autosomal causes of ID, as well as more complex etiologies. Although additional clinical features can be used to direct the diagnostic flowchart of tests ordered and this can improve the success rate of finding mutations (6), at this time, the causative mutation will go undetected in a significant fraction of patients even when whole genome array CGH, Fragile X testing, and extensive sequence analysis of the X chromosome are performed.

Also of note for clinical diagnostic testing is the fact that XLID is a clinically heterogeneous condition, making it difficult to judge whether a rare sequence variant or CNV causes disease (138,139). Clinical interpretation of rare genetic variation is further complicated when parental samples, extended pedigrees, and/or large, ethnically matched control samples are unavailable (138). Indeed, disease-causing variants in the X-linked genes make up

only a fraction of the rare, nonsynonymous variants present on the chromosome (7). The high prevalence of nonrecurring, private genetic variation on the X chromosome that is observed in families with ID makes this a large challenge for diagnostics, even when the variation is truncating or de novo (140). In fact, nonpathogenic, truncating sequence variants were found in up to 1% of X genes in the GOLD consortium study (141). These were judged to be nonpathogenic, based on additional analysis of family members and controls (7). Additional studies designed to look at rare variation are needed in order to understand the sequence variation that each X-linked gene can tolerate in an intellectually normal individual.

As with genetic variation in the rest of the genome, interpretation of sequence variation and CNV on the X chromosome can be informed through examination of segregation of the variant through a family, searches of databases of known pathogenic and polymorphic variation, such as the Database of Genomic Variants (<http://projects.tcag.ca/variation/>), DECIPHER (<http://decipher.sanger.ac.uk/>), dbVar (<http://www.ncbi.nlm.nih.gov/dbvar/>) and dbSNP (<http://www.ncbi.nlm.nih.gov/SNP/>). Unique to the interpretation of X-chromosome variation is the use of analysis of X-inactivation patterns in carrier females. Skewed X-inactivation patterns in carrier females are common with XLID mutations (142), so the observation of skewed X inactivation in a female carrier of a genetic variant on the X chromosome can be used to support its role in ID.

Although we are still likely to come up empty-handed, determining the underlying genetic explanation of XLID is an important goal to pursue in the clinical setting. A molecular diagnosis can allow for more specific prognosis and medical management, it can put an end to unnecessary testing and evaluation, and—for the family—it allows for more accurate risk assessment and for referral to specific support groups. Even without a molecular diagnosis, the recognition that the ID in a family is likely to be X-linked changes the calculated reproductive risk for siblings of an affected male from 1–2 to 10% for sisters of two affected brothers (42). With a defined molecular diagnosis, this reproductive risk can increase to 50% following carrier testing in sisters of affected males with a known X-linked mutation or CNV.

### 107.3.7 XLID Genes

An overview of the genes that have been implicated in XLID can be found in Table 107-5. Because a full description of each of these genes is beyond the scope of this chapter, we restrict the following discussion to those genes that are believed to be the most commonly mutated or for which the underlying pathogenic mechanism is at least partially understood.

**107.3.7.1 ARX.** Mutations in ARX are one of the most common causes of XLID. In the EuroMRX sample, ARX

mutations accounted for 7.5% of families with an obligate carrier female and 1.5% of affected brother pairs (6). ARX encodes a homeobox-containing transcription factor, and mutations in the gene have been associated with a range of phenotypes, all of which share ID as a consistent feature (143). At the milder end of the spectrum are cases with nonsyndromic ID, but ARX mutations can also cause brain malformations, such as lissencephaly, hydranencephaly, or agenesis of the corpus callosum. ARX mutations have been implicated in various syndromes, including Proud syndrome (agenesis of the corpus callosum with abnormal genitalia; MIM 300004), hydranencephaly with abnormal genitalia (MIM 300215), X-linked lissencephaly, Partington syndrome (XLID with dystonic hand movements; MIM 309510), and X-linked West syndrome (early infantile epileptic encephalopathy; MIM 308350). In general, the more severe the mutation, the more severe the phenotype, but one must be aware that missense mutations in key residues can cause a phenotype at the more severe end of the spectrum (143). In families in which affected males have a non-malformation phenotype, carrier females are generally unaffected. In those families with a more severe phenotype due to ARX, carrier females can be affected, albeit more mildly (143).

By far, the most common pathogenic mutation in ARX is a recurrent 24-bp duplication in exon 2 that expands a polyalanine tract. This duplication mutation is most often associated with NS-XLID, but it can also be found in patients with other phenotypes on the milder end of the spectrum, such as West or Partington syndrome (144). Although the relatively large contribution of ARX mutations to XLID overall suggests it is valid to screen ARX in cases of idiopathic ID, the frequency of ARX mutations in sporadic cases of ID is thought to be quite low (145,146). The likelihood of finding an ARX mutation is increased in patients in whom epilepsy or dystonia accompanies their ID (147).

**107.3.7.2 MECP2.** Mutations in MECP2 were originally reported in girls with Rett syndrome, and it was believed that, in boys, mutations in the same gene were not compatible with life (148). Subsequent research indicated that MECP2 mutations could also be found in boys, most often manifesting as a severe neonatal encephalopathy, but also as nonsyndromic ID (149). Early population-based studies suggested this might be as common a cause of XLID as FXS (150), but other groups have found that MECP2 mutations are not a common cause of NS-XLID and that interpretation of MECP2 sequence results is complicated by the existence of rare sequence variation in MECP2 that can be ruled out as pathogenic through careful segregation analysis in affected families (151). Some have suggested that MECP2 sequencing is not indicated in boys with ID unless there is unexplained familial XLID, if the boy had severe congenital encephalopathy, or if there is also a girl in the family with Rett syndrome (152). Others advise

*MECP2* sequence analysis in males with ID if there are progressive neurological manifestations (153). *MECP2* mutations have also been found in individuals with an Angelman syndrome-like phenotype and are believed to account for perhaps 3% of individuals referred for Angelman syndrome testing who did not have a methylation defect at chromosome 15q11–q13 (154).

Submicroscopic duplications at Xq28 that range in size from 0.3–4Mb and encompass the complete *MECP2* gene have been reported in males with ID (155). These individuals typically have moderate to severe ID and infantile hypotonia, as well as ataxia or an ataxic gait (137). Other features can include autistic features, recurrent infections, epilepsy, progressive spasticity, and sometimes developmental regression (155). As mentioned above, *MECP2* duplications account for ~1% of XLID, but this fraction may approach 15% in samples of males with ID and additional features of *MECP2* duplication syndrome, such as progressive spasticity (155). The duplication is also found in ~2% of males who were referred for *MECP2* mutation analysis but were negative for a mutation (137).

Although there is variable expressivity, the *MECP2* duplication syndrome is 100% penetrant in carrier males (155). The majority of affected males inherit the duplication from carrier females, who exhibit extreme to completely skewed X inactivation (156). Although carrier females do not have the same syndrome as their affected sons, they are likely to have psychiatric symptoms that can include anxiety, depression, and compulsive behaviors (156).

**107.3.7.3 SLC6A8.** The *SLC6A8* gene at Xq28 encodes a creatine transporter. Mutations in this gene cause one of the three cerebral creatine deficiency syndromes, which all share ID, speech/language delay, and seizures as common features. Males with *SLC6A8* mutations have ID that can range from mild to severe; the phenotypic spectrum is—not surprisingly—broader in carrier females, some of whom exhibit no obvious phenotype, whereas an estimated 50% have learning and behavioral problems that can range from mild to severe (157,158). Studies of families with XLID, or at least affected brother pairs, suggest that mutations in *SLC6A8* are one of the more frequent causes of XLID, accounting for an estimated 1–2% of XLID (159–162). Mutations in *SLC6A8* are associated with an increased creatine:creatinine ratio in urine, so it has been suggested that urine screens be used in males with ID to determine those that are a good candidate for *SLC6A8* sequence analysis (159). The creatine signal in the brain can also be assessed using proton magnetic resonance spectroscopy, and a low or absent signal can be used to guide molecular testing in boys with developmental delay, as well (163). Although creatine supplementation is used to treat the autosomal recessive forms of creatine deficiency, this is not of value in patients with the creatine transporter defect (157).

**107.3.7.4 Additional Genes.** Efforts to sequence large proportions of the X chromosome in large samples of XLID families have yielded several new XLID genes. Mutations in some of these genes are estimated to account for a significant proportion of XLID families, although, for many of the genes, it remains to be seen whether these estimates hold true when additional less-selected samples are tested. For virtually all of the genes, it is not known how frequently mutations will be found in sporadic cases of ID. These genes include: *CASK*, *PQBP1*, *IQSEC2*, *OPHN1*, and *JARID1C*. As XLID sequencing panels are developed and used in a more random sample of people with ID, we will have further insight into the relative frequency of mutations in each of these genes and into the clinical spectrum associated with mutations in each gene. Deletions and duplications have also been reported that include some of these genes, but, again, the frequency of these copy number changes in individuals with ID is unknown. As is indicated below, certain aspects of the clinical picture can be used to direct molecular testing for XLID, but until we collect a significant number of patients with mutations in any particular gene, it is hard to clearly define the phenotypic spectrum associated with mutations in any one gene, so, to begin, we must cast a fairly wide net in looking for mutations, although this will generally result in a low yield (164).

*CASK* encodes calcium-calmodulin-dependent serine protein kinase. Mutations in *CASK* were originally described in girls with severe ID, microcephaly, and cerebellar hypoplasia, and a boy who died at 2 weeks of age, leading to the idea that *CASK* mutations are dominant with reduced viability in boys (165). Subsequent research indicates that this may be true for severe, loss-of-function mutations in *CASK*, but that reduced function mutations are found in boys with ID. Tarpey et al. (7) found mutations in boys from four of 358 XLID families (1.1%) in the GOLD consortium sample. Congenital nystagmus was present in affected individuals from two of the original families, which led the researchers to subsequently look for mutations in *CASK* in 45 additional probands with ID and either nystagmus or microcephaly; 2 of the 45 probands (4.4%) had mutations in *CASK* (166). Thus, the presence of nystagmus in a boy with ID may be considered an indicator for *CASK* sequence analysis.

The GOLD consortium has also provided evidence that *CUL4B* could be a significant cause of XLID (167). They identified mutations in 8 out of 250 XLID families (3%). *CUL4B* encodes a ubiquitin E3 ligase. In addition to ID, boys with mutations tend to have macrocephaly, short stature, seizures, and aggressive outbursts (167).

The *IQSEC2* gene is another gene identified by extensive sequencing in the GOLD families (168). Four missense mutations were identified in 208 XLID families (1.9%). Mutations appear to be associated with language delay, seizures, and autistic features.

Mutations in *OPHN1* were first found to cause ID in the EuroMRX sample. *OPHN1* encodes oligophrenin 1,

a Rho-GTPase-activating protein. Mutations have been found in probands from families considered to have NS-XLID, but MRIs of affected individuals have documented cerebellar hypoplasia and dysplasia of the vermis (169). This led Zanni et al. to suggest that neuroradiologic investigation of individuals with ID be used to detect subtle brain abnormalities that could be used to direct molecular diagnostics (169). In the EuroMRX set, three of 63 families with obligate female carriers (4.8%) have mutations in *OPHN1*, and a similar fraction of families with affected brother pairs in their sample (3 of 65; 4.6%) have mutations in this gene (6).

Mutations in *PQBP1* have been found in both syndromic and nonsyndromic forms of XLID. This includes Renpenning syndrome, an XLID syndrome that includes microcephaly, small testes, and short stature (170). There is a wide clinical spectrum associated with mutations in *PQBP1*, and this can also include congenital heart defects and craniofacial abnormalities (171) and microphthalmia (172). Of 111 XLID families with obligate carrier females in the EuroMRX sample, de Brouwer et al. found five with mutations in *PQBP1* (4.5%); on the other hand, no mutations were found in 73 families with affected brother pairs or in 465 sporadic male cases of ID (6). A study by Jensen et al. again found a lower mutation frequency (0.7%) in families with fewer affected boys; one of 135 families with no more than two affected brothers was found to have a *PQBP1* mutation (160).

Mutations in *JARID1C* were originally found in 5 of 179 families from the EuroMRX sample (2.8%) (173). Further analysis of 144 NS-XLID families also collected through EuroMRX identified five *JARID1C* mutations, a frequency of 3.5% (174). This frequency did not hold up in all samples; Abidi et al. found one mutation out of 172 general XLID probands (0.6%) (175). Use of short stature as a selection criterion might increase this frequency; 1 of 92 probands with ID and short stature (1.6%) was found to have a *JARID1C* mutation (175). Finally, 2 of 208 XLID families (1%) in the GOLD sample had a mutation in *JARID1C* (176). Pooling data from all published individuals with a mutation in *JARID1C* indicates they have ID that ranges from mild to severe, as well as a clinical picture that can include short stature, seizures, hyperreflexia, and microcephaly (176). Carrier females can be mildly affected.

### 107.3.8 Disease Mechanisms

**107.3.8.1 ATRX.** Mutations in *ATRX* cause a spectrum of ID phenotypes with the classic presentation being the alpha-thalassemia XLID (*ATRX*) syndrome. *ATRX* syndrome can be recognized by characteristic facial features in the presence of (typically) severe ID and an unusual form of alpha-thalassemia. The facial features include midface hypoplasia, a tented upper lip and full, everted lower lip, upswept frontal hair, and a protruding tongue (177). The alpha-thalassemia is unusual in

that peripheral red blood cells contain hemoglobin H inclusions that can be used in the diagnosis of the syndrome (178). Mild skeletal abnormalities can also be present, such as clinodactyly, brachydactyly, tapered fingers, pes planus, clubfoot, and scoliosis (177). Postnatal microcephaly, sensorineural deafness, and seizures may also occur (178). Although affected individuals have a 46,XY karyotype, genital abnormalities are common and range from hypospadias to external female genitalia (pseudohermaphroditism). The range of syndromes associated with *ATRX* mutations encompasses: Carpenter–Waziri syndrome, Holmes–Gang syndrome, Chudley–Lowry syndrome, and XLID with spastic paraplegia, and these can be considered part of the same spectrum (179). Female carriers are intellectually normal and do not have consistent physical manifestations, due to marked skewing of X inactivation (177).

The *ATRX* protein is a member of the SWI/SNF family of DNA helicases that remodel chromatin. *ATRX* plays roles in sister chromatid cohesion during mitosis and in regulation of gene expression (180). The MECP2 protein recruits *ATRX* to pericentromeric heterochromatin (181), and these proteins seem to work in conjunction with cohesin to regulate postnatal expression of certain imprinted genes in the brain (180). The majority of mutations associated with *ATRX* syndrome are point mutations in the exons encoding the helicases and zinc-finger domains, although mutations do exist in other parts of the gene (179). Duplications and deletions of the gene have been reported less frequently.

The severity of the alpha-thalassemia component of the *ATRX* syndrome can be quite variable, even within a single family, and is due to decreased expression of the  $\alpha$ -globin locus on chromosome 16. This variability was puzzling given that individuals within a family would share the defect in *ATRX*. *ATRX* binds to a variety of sites across the human genome, including many gene promoters associated with CpG islands (182). One of these is a region approximately 1 kb upstream of the  $\alpha$ -globin gene *HBM* within a variable nucleotide tandem repeat (VNTR). The length of this VNTR is quite variable within the human population, and it is this second site variability that determines the severity of alpha-thalassemia in individuals with the *ATRX* syndrome. In the absence of *ATRX* expression, the VNTR exerts a repressive effect on transcription of *HBM*, and the longer the VNTR, the greater the reduction in  $\alpha$ -globin expression (182).

**107.3.8.2 XLID Pathways.** Many of the XLID genes encode proteins involved in basic cellular processes, including transcription regulation, metabolism, RNA processing, DNA metabolism, telomere maintenance, and the ubiquitin cycle (183). Several examples exist in which multiple ID genes work together in the same pathway, providing a potential common underlying mechanism for the development of ID. As mentioned above, MECP2 recruits *ATRX* to certain heterochromatic regions and works with the cohesin complex, a component of which

is encoded by *SMC1L1*, to regulate gene expression (180). Another example involves the XLID genes *PHF8*, *ZNF711* and *JARID1C*. *PHF8* is a demethylase that acts on di- and monomethylated lysine 9 of histone H3 that binds near transcription start sites of active or poised genes (184). Chromatin immunoprecipitation followed by DNA sequencing indicates that *PHF8* binds to a number of XLID genes, including *JARID1C*, *ZNF41*, and *ZNF81*. *PHF8* is recruited to some of these sites by the zinc-finger protein *ZNF711*, which is encoded by another XLID gene. The two proteins, together, bind at *JARID1C* and influence its expression (184). The linking of XLID genes in the same cellular pathway adds to our understanding of the processes that lead to ID and hint that other components of the same pathways may also be candidate ID genes.

## 107.4 CONCLUSION

The development of array CGH and the increase in our DNA sequence capabilities has led to an explosion in the number of genes and genomic regions that have been implicated in XLID. Right now, we are at a point where we have greater ability to identify CNVs and sequence variants than to interpret them, leaving us at a disadvantage in clinical diagnostics for XLID. In order for us to fully understand the tolerance for genetic variation on the X chromosome, it is crucial that sequence and copy number analysis could be performed in additional large samples of individuals with ID, particularly sporadic cases, and this could be linked to our understanding of variation in the normal human genome, which is coming from projects such as the Thousand Genomes Project, so that we can fully understand the tolerance of the X chromosome for variation. However, we should not downplay the fact that we can uncover the relevant genetic change in an increasing number of cases of ID, both inherited and sporadic, and that sequence analysis of a large number of XLID genes is available on clinical testing panels.

### ABBREVIATIONS

SRD – specific reading disability  
SSD – speech sound disorder  
SLI – specific language impairment

### 108.1 INTRODUCTION

Nonsyndromic language/learning disorders are heterogeneous in presentation or symptomatology, life course, and etiology. Diagnostic criteria may vary depending on the examiner and the reason for the examination. Criteria that qualify a child for special education for learning disabilities may be quite different from the criteria for research into the underlying causes. Furthermore, there are no biologic tests for these types of disorders to date. Nevertheless, standards for diagnosis (e.g. the Diagnostic and Statistical Manual of Mental Disorders, 4th edition text revision (DSM-IV-TR)) do exist, and there is convincing evidence for organic and genetic etiologies. This chapter deals with the most common nonsyndromic learning disorder that is likely to confront physicians and geneticists: specific reading disability (SRD or dyslexia). Dyslexia is the most intensively studied childhood learning disorder from a genetic standpoint and appears to be related to other language and learning disorders, thus providing a model for further research into their causation and etiology.

### 108.2 DEFINITION

Specific reading disability is an unexpected difficulty learning to read (and/or spell) despite adequate intelligence and

opportunity and without demonstrable sensory, psychiatric, or neurologic factors that could explain the disorder. This definition, like that for many learning disorders, is exclusionary in that other causes of reading problems have been ruled out (e.g. emotional problems or environmental deprivation). It is noteworthy that there is a push in the field to start to define SRD more in terms of inclusionary symptoms, although a finite or gold-standard set of inclusionary criteria has yet to be accepted and there are arguments to support the idea that at least some exclusionary criteria may always be needed (45).

The diagnosis of SRD usually requires a measured discrepancy between reading or spelling ability and the level of the skills that would be expected based on age or intelligence. For example, the US federal definition of learning disabilities specifies a discrepancy of 1 standard deviation (SD) in achievement (e.g. reading) and ability (e.g. a standard measure of intelligence) (181); these are often used as criteria to qualify a child for additional educational services. Other definitions have required varying deficits in reading achievement, such as 2 SD below the mean for age or 2 years' delay for age or grade (116). Of course, this variation in phenotypic definition will affect estimates of prevalence.

A task force of investigators representing the International Dyslexia Association and the National Institutes of Health adopted the following version of a research definition of dyslexia in 2002.

Dyslexia is a specific learning disability that is neurological in origin. It is characterized by difficulties with accurate and/or fluent word recognition and by poor

spelling and decoding abilities. These difficulties typically result from a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction. Secondary consequences may include problems in reading comprehension and reduced reading experience that can impede growth of vocabulary and background knowledge (99).

SRD is essentially the same as dyslexia, although the term dyslexia has been avoided by some because of additional connotations that have been attached to it in the past, such as right-left confusion, left-handedness, and reversals of letters and words. More recent studies have shown that these associated problems are certainly not pathognomonic of dyslexia and may not be greatly increased over the general population (9,12,116). Alternate terms are “specific dyslexia,” which emphasizes the lack of deficit in other areas of cognitive functioning; “developmental dyslexia,” to differentiate it from acquired causes such as trauma or stroke; and “reading retardation.” In contrast, “reading backward” or “garden-variety poor reading,” has been used when the reading level is consistent with generalized cognitive delays (44,116,142).

Initially, there was debate as to whether dyslexia actually exists as a separate learning disorder (44,116,141,157). It was argued that the poor reading in children with below-average intelligence quotient (IQ), or in whom there is no significant IQ-achievement discrepancy, is not qualitatively different from the poor reading seen in dyslexia (157). Some researchers maintained that, if dyslexia is etiologically distinct, it should produce a “hump” in the lower end of the otherwise continuous distribution of reading scores in children (169,192), but several studies did not detect such a hump (137,157).

As will be reviewed later in this chapter, genetic and linkage studies hold promise toward defining the phenotype more precisely; for example, the heritability of dyslexia is greater in a population selected for higher IQ (185), suggesting that broader definitions of SRD may include a number of factors that may depress cognitive functioning overall that are not specific to SRD. Moreover, at least for a locus on chromosome 6p22, linkage is more significant in populations with more severe dyslexia (49,55) or higher IQ (85).

### 108.2.1 Prevalence

Estimates of the prevalence of SRD depend on the definition used, the age of the population, and the language or culture examined. For example, more children with reading problems will be identified in first grade because of different rates of maturation; however, by third grade, many of those children will have caught up with their peers in reading ability. This catch-up phenomenon was demonstrated by Shaywitz and colleagues (157) and cited as evidence that SRD is an unstable trait. Huston (76) argued in response to this study that those children

who improved between first and third grade did not have dyslexia; those with persistent problems were the true dyslexics. Moreover, test-retest unreliability, which was not taken into account, could make a substantial contribution to the instability of the dyslexia diagnosis over time. Overall, typical estimates of prevalence of dyslexia in school children in third grade or beyond have been 5–10% (5,83). Similar estimates have been found for logographic languages such as Chinese (86). If a broader definition of poor reading is used that does not require a significant discrepancy with nonreading abilities, the prevalence may be as high as 20–30% (6,34); in contrast, in populations in which the written language is more phonetically consistent, such as Italian, the frequency of diagnosis of dyslexia is lower (115,181).

### 108.2.2 Sex Ratio

Clinically referred populations generally show male:female ratios from 3:1 to 6:1, but this appears to be due mainly to biases in referral favoring males, or to the effects of increased severity in males. In systematically ascertained populations of boys and girls, the male-to-female differences have not been as pronounced. For example, Shaywitz and associates (156) diagnosed dyslexia in 8.7% of the boys and 6.9% of the girls in a second-grade epidemiological sample, while their teachers identified 13.6% of the boys and 3.2% of the girls as disabled readers. Similarly, Wadsworth and colleagues (184) found equal proportions of affected boys and girls when the probands were ascertained by research criteria, rather than being part of a clinically referred population. In affected members of families ascertained through an SRD proband, the sex ratios are typically around 1.3–1.7:1, once ascertainment bias is corrected by elimination of probands. Although the trend toward excess males may remain, typically the sex ratios in well-defined research samples are not significantly different from 1:1 (24,133).

### 108.2.3 Natural History and Life Course

Although generally considered to be a school-age disorder, there is evidence that underlying language-based problems can be noted in the first few years of life, and signs and symptoms of dyslexia persist into adulthood. In a unique prospective study Scarborough (145) ascertained a sample of 34 children aged 2 years with a positive family history of reading disability, and matched them to 44 children with a negative family history. They were given a series of language tests over a 6-year span, and reading ability was assessed in second grade. As would be expected from the familial nature of SRD (see following paragraphs), 22 of the 34 children with a positive family history became poor readers, while only 2 of the 44 children of control families were poor readers. Moreover, the 22 poor reading children with a positive family history of SRD showed early language problems

that were not seen in the other 12 high-risk children who became normal readers. In fact, the early language abilities of the children who later became normal readers were indistinguishable from the controls. At 30 months of age, the children who became dyslexic had deficits in syntax that were correlated with later phonologic problems. At 42 months, they had poorer vocabulary scores, and at 5 years of age, they had deficits in vocabulary and letter/sound correspondence. By contrast, receptive phonologic skills were normal. Perhaps the most interesting finding of this study is that the dyslexic children showed a marked disinterest in books even before reading instruction was introduced to them. Differences in how often parents read to them were not large enough to account for this difference; rather, the children over 36 months of age were much less likely to seek out books themselves (146). The extent to which this lack of interest in reading is genetic is unclear, however. It is possible that this represents active genotype/environmental correlation (147); that is, a child with genetic susceptibility to SRD may tend to select nonreading activities. This has been referred to as “niche-picking” (61,126).

Prior to school age it is not uncommon to observe oral language problems in children who develop reading disability, and some have estimated that approximately 50% of SRD children had language problems before attempting to learn to read (17). The primary reading-related symptoms of SRD are noted in the first few school grades. These symptoms are particularly evident in oral reading and in learning to spell phonetically, and the children may produce unusual reading and spelling errors. Specifically, they produce a higher proportion of phonologically inaccurate errors than non-SRD children. In reading, they will substitute words that begin with the same letter as the target word, but otherwise are pronounced differently. In spelling, they will produce a misspelling in which consonants are missing, added, or substituted. Reading comprehension is closer to normal, particularly when the child is not pressured to read quickly. As reviewed by Pennington (116) and Lefly and Pennington (88), the correlated features of dyslexia, related to the underlying language disability, are articulation problems, problems with naming, and verbal memory deficits. Naming and verbal memory deficits may be secondary to the reading and phonological problems, since these skills are not deficient when compared to younger reading-age-matched controls. Letter and number reversal, usually thought of by lay people as important signs of dyslexia, are actually secondary to the phonologic confusion between the sounds the letters represent and are, in fact, developmentally normal early on as the child acquires reading skills. In contrast to the language difficulties, ability in arithmetic is often much better, as long as reading-related skills are not required.

The reading and spelling problems seen in childhood generally persist in the later grades. In a longitudinal study in which children with SRD were periodically

tested into their late teen years, reading ability stayed below that of controls. The gap between the two groups actually widened for symbol processing speed, perhaps because of lack of remediation in this particular skill (86). Similarly, a longitudinal study by Shaywitz and associates (155) documented that twelfth graders who had reading disability since elementary school still showed reading delays. These were related to phonological deficits (that is, the auditory, “phonetic” aspects of language, discussed in detail later in this chapter), and reading rate remained slow. Interestingly, reading comprehension was not important in discriminating the poor readers from average or superior readers. Although the high school seniors with reading disability had poorer academic achievement, there was no indication of behavioral problems. Two other studies of morbidity of behavior problems and reading disability also showed that the two were independent, and that often the behavior problems could be noted to predate reading disability (37,142).

Finally, SRD has been documented to have an effect on adult outcome. Finucci (40) reviewed a number of follow-up studies, most of which indicated a detrimental effect of SRD on educational attainment and occupation; however, several studies, including her own, indicated that severity of the dyslexia, IQ, and socioeconomic status also had significant influence on outcome. For example, individuals with dyslexia could succeed in college, but they generally took longer to complete the requirement for a degree and chose occupations with less demand on reading.

It has been questioned whether dyslexia represents a “developmental lag,” which would mean that children with SRD actually read like younger normal children and eventually attain more age-appropriate reading ability at a later age, or whether it represents a deficit that is qualitatively different and that is persistent into adulthood. The studies previously cited by Finucci (40), LaBuda and DeFries (86), and Shaywitz and associates (155) demonstrate that the effects of SRD do persist into adulthood, with a plateauing of reading ability. A number of other studies have also reported continued reading problems or have found deficits in underlying skills in adults with histories of SRD, including phonologic processing, selective auditory attention, naming, and short-term memory similar to those found in children with SRD (10,11,110,143,154). Others have noted that adults may exhibit a variety of symptoms related to their learning disability but not obviously or commonly associated with, say, a reading problem. These “subtle” clinical markers that may indicate a referral for a learning assessment include frequent tardiness, difficulty with mental math, avoidance of reading, poor sense of direction, and forgetfulness, among others (see Appendix 5 of Reference (135)).

Some adults do fully compensate for their childhood reading problems; that is, they attain expected reading

levels and are no longer diagnosable as dyslexic via standardized tests of reading/spelling-related errors. Several studies have reported compensation rates of approximately 22%, with slightly more females compensating than males (61,88,119,143,144). While the reading level that SRD children attain as adults may be related to IQ, education, and SES (36,59,63,143,144), underlying problems can still persist independent of these factors. For example, Lefly and Pennington (88) found that compensated adults who had reading levels similar to those of control adults had deficits in reading speed that were comparable to those in adults who were still dyslexic.

Most studies of adult outcome and compensation have relied on a self-reported diagnosis of dyslexia. While self-report is fairly reliable (63), the degree and specificity of the childhood reading problems often cannot be documented. The follow-up studies of Wood and Felton and their colleagues at Bowman-Gray School of Medicine are unique in that childhood test results are available on a group of adults diagnosed as dyslexic in childhood between 1957 and 1972. This has allowed the researchers to relate adult outcome to the severity of the SRD in childhood. Felton and colleagues (36) found that the severity of the reading problems in childhood predicted severity as an adult, while more mildly affected children were more likely to become compensated adults. Adults who were still dyslexic performed poorly on several neuropsychological tests compared to controls, but they were also found to have somewhat lower IQ, socioeconomic status, and educational achievement. When these factors were controlled, only phonologic tasks and rapid verbal retrieval were still significantly impaired.

One caveat in accepting outcome and rates of compensation from older studies is that the methods of remediation may have been less effective than the phonologically based methods currently used. In fact, Shaywitz and colleagues (155) noted that the remediation that had been available to their twelfth grade students when they were in elementary school in the early 1980s was sporadic and inconsistent in approach, which may have contributed to some of the persistence of reading problems.

### 108.3 PRIMARY COGNITIVE DEFICIT OF SPECIFIC READING DISABILITY

In the history of research in reading disability, it has generally been assumed that SRD is etiologically heterogeneous, and that identification of subtypes would aid in the development of appropriate remediation strategies for each type. Classification systems were developed based on clinical features or theoretical models of the reading process. Initially, the subtypes generally related to whether the predominant errors in reading and spelling seemed to reflect phonological problems (“auditory dyslexia,” “dysphonetic dyslexia,” “deep dyslexia”) or problems with visualization of words (“visual dyslexia,” “dyseidetic dyslexia,” “orthographic

dyslexia,” “surface dyslexia”). Phonologic problems can be conceptualized as difficulty attaching sounds to letters, resulting in particular problems sounding out unfamiliar words. This can be assessed by the ability to read “nonsense” words, which are phonetically regular and pronounceable, but are not real words, so that visual pattern recognition of the word is not involved in reading it. Conversely, orthographic problems are characterized by difficulty reading words based on their appearance, so that irregularly spelled words are not recognized, but words can be sounded out. This is tested by the ability to read “irregular” words in which the pronunciation does not match the phonetics, such as the word “yacht.” These words must be recognized by their appearance, since use of a phonological approach will be misleading. (Note that orthographic disability will be a problem primarily with languages with irregular spelling patterns, such as English.) These contrasts between phonological and orthographic abilities are also seen in acquired alexia, which is an inability to perceive/read written words, related to specific lesions of the brain (15). However, when subtypes of dyslexia were defined and children were categorized by whether they showed phonological or orthographic errors, it was found that the assignment was not always consistent within families or even in the same child over time, leading Snowling (165) to conclude that subtype classifications appeared to have more descriptive rather than etiologic utility. The contrast between phonological and orthographic processes has remained, however, in the efforts to determine if these represent two independent pathways to reading and if one or the other is more basic and more heritable.

Pennington and colleagues (121) have reviewed the theories that have related phonology and orthography. Initially, theories of learning to read took a hierarchical approach; normal readers were thought to rely first on phonologic skills, through slow and methodical “sounding out.” This process would reach a plateau and would be superseded by reliance on faster orthographic processes to facilitate word recognition. Dyslexics, it was postulated, could be blocked at either the phonologic or orthographic stage. This led to methods of remediation that concentrated on enhancing the orthographic stage, by teaching whole-word recognition. The results were dismal, and further research demonstrated that even skilled, mature readers utilized phonology for reading. In fact, the “dual process” theories of reading further declined when it appeared that phonological skills were deficient almost universally in reading-disabled children and adults, even when compared to younger controls reading at the same level as the dyslexics. Consensus built that phoneme awareness, the ability to understand and manipulate the basic sounds of language, was likely to be the primary deficit in reading. When matched on word reading and spelling accuracy, dyslexics do make more orthographically plausible errors in their spelling

attempts than younger controls whose errors tend to be more phonologic in nature, suggesting that orthographic knowledge is influenced by greater experience with text (48). The predominance of phoneme awareness as an underlying deficit in reading disability did not mean that orthographic skills were normal, however. In the majority of disabled readers, both skills were delayed (15).

In an effort to resolve the relationship between these two processes, Pennington and colleagues (118) and others have drawn upon the connectionist theory of Seidenberg and McClelland (153). This is a type of neural network design in which the input is the visual image of the word and the output is the recognition and pronunciation of the word. A three-layer network is hypothesized that contains both phonological and orthographic layers, and through the learning process, the network develops the interconnections to create a balance between both processes in deciphering a word. If any of the interconnections are faulty, the input is degraded, or there is too much reliance on one process at the expense of another, reading problems result (101). More detailed cognitive models are reviewed by Ramus (130).

It is important to mention two other aspects of reading disability that may constitute etiological subtypes. Wolff and colleagues (summarized in Reference (189)) have noted that about 50% of familial dyslexics show impairment in precise coordinated motor action in both manual fine-motor tasks and in speech, and that this constitutes a subtype that is consistent within families. In addition, Stein and colleagues (summarized in (168)) have described a small subset of dyslexics who report distinctive visual perceptual problems, such as seeing letters move on the page. These individuals show problems with vergence, and patching one eye appears to improve their vergence and reading ability. These reports, and others, suggest that reading or phonological awareness as the “pure phenotype” of a dyslexic individual may be complicated by other symptoms reflecting a complex neurological difference in these individuals (56,62). These data are examined further in the following sections.

In sum, the proper models for reading acquisition and the underlying cognitive deficits in dyslexia have not been fully determined, although phonological processing does appear to be the predominant deficit. The contributions and interactions of auditory and visual systems are now being assessed at neurological levels, and genetic studies are demonstrating that a single genetic locus can affect both orthographic and phonologic phenotypes at once (43,54–56,62).

## 108.4 INHERITANCE

The familial nature of reading disability was noted around the turn of the century, and numerous reports of multiplex families followed (e.g. (71); see reviews by Fisher and DeFries (42), DeFries and Gillis (28), DeFries and Alarcón (24), and Schulte-Korne (149). Systematic

family and twin studies have demonstrated genetic influences underlying the familial transmission.

### 108.4.1 Twin Studies

Although many twin studies of reading disability have been reported, a number of early studies suffered from poor measurements, small sample size, and/or biases in the ascertainment of twins (see Harris (71) and DeFries and Gillis (28) for reviews). The Colorado Twin Study of Specific Reading Disability, which was initiated in 1982, has avoided these problems, and has reported proband-wise concordance rates for SRD of 68% and 38% for monozygotic (MZ) and dizygotic (DZ) twins, respectively (24). This significant ( $p < 0.001$ ) difference confirms earlier reports of genetic influence in SRD.

DeFries and Fulker (25,26) have presented a method using regression analysis rather than concordance rates to examine quantitative differences between MZ and DZ twin pairs. An extension of this method can assess the genetic influence on extreme phenotypes, such as deficit in a quantitative phenotype. This method, which can be used for many complex phenotypes, involves the selection of a sample of MZ and DZ twins such that at least one member of each pair (i.e. the probands) exceeds a predetermined extreme on the phenotype. The extent to which the extreme performance of the probands is heritable ( $h^2_g$ ) can be measured by the degree to which their MZ or DZ co-twins regress toward the unselected population mean. Specifically, if deficits in performance are to some extent heritable, MZ co-twins should regress toward the mean less than their DZ counterparts. Using this methodology with a composite discriminant score of reading ability, the Colorado Twin Study reported an  $h^2_g$  value of approximately 0.56 (SE = 0.09) (24,28).

Twin studies have also been used to help resolve the phenotype of SRD. Using data from the Colorado twins, Pennington and colleagues (119) demonstrated that the requirement for a significant discrepancy between reading and intelligence may not define a genetically unique disorder, at least in children with normal intelligence. The twins had been selected such that at least one member of each pair was reading disabled according to school records, and then additional testing was done. All the twins had an IQ greater than 90. Two diagnostic criteria were applied, one based on age discrepancy with reading achievement (“backward readers”) and the other on IQ discrepancy (“true dyslexics”). It was found that both definitions of reading disability were moderately heritable, with  $h^2_g$  quotients of approximately 0.47. Furthermore, reading ability was highly correlated between both types of SRD ( $r = 0.93$ ), and this correlation was primarily due to shared genes. (Ninety-two percent of the covariance in reading ability between the two diagnoses was explained by a common genetic origin.) This suggested that the age and IQ diagnostic phenotypes both detected the same, etiologically related reading disorder in this

population. Thus, the argument for an etiologic distinction between backward and specific dyslexics may not be as tenable as was once proposed, at least in individuals with normal intelligence (192). Similar conclusions have been reached in the psychometric literature (44).

Olson and associates (112) have also used this sample of twins to examine the heritabilities of orthographic and phonologic reading and spelling skills. In a sample of 296 MZ and DZ twins, it was found that both skills were again equally heritable. The estimate of  $h^2_g$  for orthographic coding was 0.56 (SE 0.13), quite comparable to 0.59 (0.12) for phonologic coding. Using a bivariate analysis (selection of a proband based on deficit on one skill, and assessing heritability based on measures of the other skill), it was demonstrated that deficits in both skills were influenced primarily by the same genetic effects (53). Furthermore, both skills were related to phonologic awareness, with  $h^2_g = 0.60$  (0.17), and appeared to be the skill least influenced by shared family environment (i.e. family influence that will tend to make relatives alike, or  $c^2$ ). Enlarging the sample to 440 pairs of twins confirmed that phonologic and orthographic coding skills had shared as well as independent genetic influences (54). Thus, it would appear that these are not totally separate, modular skills, a conclusion that supports the neurological evidence of independent “dual route” as well as shared “connectionist” pathways.

Additional studies of the same twin sample (although expanded in size) examined whether subgroups classified as “phonologic” or “surface” (orthographic) had different heritabilities (16). If the processes were indeed independent, it was anticipated that the heritabilities would be different. Subjects were selected from the extremes of deficit in the two skills, nonsense word reading and exception word reading. Phonological dyslexics showed high heritability, with  $h^2_g = 0.67$  (SE = 0.14),  $p < 0.001$ . There was also evidence for a shared environment effect,  $c^2_g = 0.27$  (SE = 0.13),  $p < 0.05$ . Thus, genetic effects appeared to be the most important for this group. In contrast, for the surface dyslexics,  $h^2_g = 0.31$  (SE = 0.13),  $p < 0.05$ , and  $c^2_g = 0.63$  (SE = 0.13),  $p < 0.001$ , indicating that, while there was a significant heritable component for surface phenotypes, shared environment made a stronger contribution than in the case of phonologic phenotypes. This could lend support to the hypothesis that phonological skills are primary and that orthographic abilities are more sensitive to variation in environmental input, such as teaching methods or exposure to reading.

#### 108.4.2 Family Studies and Segregation Analysis

As mentioned previously, there have been many reports of families with histories of SRD. Hallgren (71) conducted the first formal study of dyslexic families and noted the high degree of familial occurrence. He used segregation analysis (as done in the day) to determine

whether the pattern of inheritance was consistent with the predictions of genetic transmission and found a fit with autosomal dominant inheritance; that is, when one parent was dyslexic, approximately half the children were also affected; however, the relatives of the proband were not actually tested to confirm the diagnosis.

One of the first family studies to carefully examine the first-degree relatives of SRD probands was done by Finucci and colleagues (41). Although multiple family members were found to be affected, the families were too few and too small to use statistical methods to establish a definite mode of inheritance. Similarly, Høien and associates (74) studied the families of 19 very carefully defined dyslexics. A positive family history of dyslexia was found in the nuclear families of 13 probands and in the extended families of 3 more. All the probands with a positive family history showed phonologic deficits when compared to matched controls, but orthographic word recognition was not delayed. By contrast, the phonologic deficits in the remaining 3 probands with negative family histories were not as severe as in the other 16. This was also a small study, and the mode of inheritance could not be determined, but all but one of the multiplex families had an affected parent.

The first segregation analysis of SRD that based the diagnosis in first-degree relatives on actual testing was done by Lewitter and colleagues (94). They analyzed the data on 133 nuclear families using a discriminant score as a continuous phenotype. When all the families were considered together, major gene inheritance could not be supported, but when the families of female probands were considered separately, autosomal recessive inheritance could not be rejected. Multifactorial inheritance was possible, but a multifactorial/threshold model (with higher threshold in females) was rejected. It was concluded that genetic heterogeneity was likely in this population, which could have masked a major gene occurring in a subset of families.

Since these early studies, more sophisticated forms of segregation analysis were developed that can consider a combination of major gene and polygenic influences (i.e. “mixed models”) simultaneously as well as correct for various statistical assumptions and sampling biases. Pennington and colleagues (120) used such a program, POINTER, and examined four sets of families from studies based in Colorado, Washington State, and Iowa, as well as a Linkage kindred sample collected specifically for genetic linkage analysis. This is the largest study of its kind to date. Evidence for a major dominant or additive gene was found for the Colorado, Washington, and the Linkage kindred samples. Segregation in the Iowa sample was more consistent with polygenic influence. This may have been due to a decrease in the accuracy of the diagnosis in more remote relatives, resulting in lower rates of affection that would mimic a polygenic model. For the dominant major gene model, penetrance in the heterozygote in the study with the most unbiased sample

(Colorado) was 1.0 for males and 0.56 for females. The Washington sample was biased toward large multiplex families and the Linkage kindred sample was selected for an autosomal dominant pattern; in those samples, the penetrance for males was still 1.0, but penetrance for females was 0.70–0.89. Estimates of the number of sporadic cases (i.e. cases of SRD without the putative dominant allele) were low; penetrance for the homozygous unaffected genotype ranged from 0.001 to 0.039 in males and was consistently 0.000 in females. While intuitively it seems unlikely that a single locus accounts for such a high proportion of SRD in the population, the results indicate that it is likely that genetic influences affect a significant number of cases.

Segregation analysis has also been performed on a quantitative measure of reading ability derived from standardized tests (59). This analysis was based on the 125 control families (i.e. selected through normal reading probands) of the Colorado Family Reading Study (94). The results were somewhat surprising: there was evidence for a fairly common major gene acting to produce normal reading variability. It was estimated that this gene accounted for 54% of the variance in normal reading ability. As in the previous segregation analysis, the authors cautioned that the analysis may have produced an overly simplistic picture. A combination of several “susceptibility” loci could mimic a single gene pattern with greater effect, and the sample size may not have been large enough to detect an additional multifactorial contribution.

More recently, segregation analyses have been used to estimate the number of genes that may contribute to dyslexia phenotypes and to determine the most likely mode of inheritance. Studies of two measures of phonological skills, phonologic coding (nonword repetition) and phonologic memory (digit span) indicated genetic influences for both. Monte Carlo Markov Chain (MCMC) analysis estimated that two to three genes contributed to nonword repetition, with a codominant mode of inheritance favored by complex segregation analysis, while one to two genes were estimated to contribute to digit span with a dominant mode of inheritance. When the digit span phenotype was adjusted by covariance by nonword repetition, the evidence for genetic influence disappeared. Adjusting the nonword repetition phenotype for digit span had little effect on the results, suggesting that the genetic influences on digit span are primarily due to the skills it has in common with nonword repetition, which are likely to involve language processes such as phonemic representation and retrieval (187). In further studies of phonologic skills, this same group has examined phonologic decoding (word attack) and phonologic decoding efficiency (a timed work attack skill). Again, both showed evidence of genetic contribution with genetic heterogeneity. Both phenotypes appeared to be influenced by one to two genes, although decoding efficiency showed greater evidence

for more than one gene in the MCMC analysis. Complex segregation analysis supported a dominant mode of inheritance with polygenic background for decoding efficiency, with polygenic inheritance for word attack. This could be due to the greater difficulty of the timed test, particularly for compensated adults in the study, and indicates that the timed task may be a better phenotype for linkage analyses geared toward detecting the major loci (19).

### 108.4.3 Linkage Analysis

As we begin this section it is worth noting that there has been a surge in the focus on finding the genes that are relevant to SRD. This research emphasis has met with some success as we will detail later. On the other hand, finding the specific shared or nonshared environmental factors that contribute to the risk for SRD has proved elusive and complex. Although several specific factors have been suggested, such as toxins, intrauterine hormones or viruses, educational opportunities, parental modeling, and others, no one factor has been shown to consistently predict SRD across samples. A better understanding of the role of the environment and its interactions with genes will be an important contribution to future work (9b 146,141,181)

Identification of a linkage of SRD with a known gene or marker would be conclusive proof of a genetic effect. Two methods of linkage analysis have been used in studies of SRD; the family study, LOD score approach (108) and studies of allele sharing between siblings, based on the sib-pair analysis of Haseman and Elston (72). In addition, definitions of phenotype have varied widely, from dichotomous affected/unaffected diagnoses to quantitative “summary” variables, to measures of phonologic and orthographic phenotypes. The results of these linkage studies have confirmed the prediction of genetic heterogeneity.

The majority of studies have focused on the first loci that were reported to show linkage, 15q and 6p. These localizations have been refined to the regions 15q21 and 6p22.2, and linkage has been confirmed by separate, independent studies. Additional studies, including several full genome screens, have suggested linkage for at least a dozen loci (Table 108-1), and five of these loci have also been replicated in independent samples (e.g. 1q36, 2p16-15, 3p12-q13, 18p11, and possibly Xq27.3).

Gene designations have been given to the nine loci for which linkage has been replicated: DYX1, 15q21; DYX2, 6p22.2; DYX3, 2p16-p15; DYX5, 3p12-q13; DYX6, 18p11.2; DYX8, 1p36; and DYX9, Xp27.3. DYX4 and DYX7 had been assigned to separate loci on chromosome 15, but currently these are subsumed under DYX1. DYX4 has also been applied unofficially to the 6q13-q16.2 locus. The current status of the major loci and the candidate genes that have been screened are summarized in the following paragraphs.

**TABLE 108-1 Gene Localization Studies with Reading Disability**

#### 108.4.4 DYX1, 15q21

Linkage near the centromeric region of chromosome 15q was first reported in 1983 (161), but was not supported by subsequent analysis by Rabin and associates (128), which included one of the families that contributed significantly to the linkage results in the Smith and colleagues study. Additional studies of more telomeric markers were positive, however (49,162), and this linkage has subsequently been replicated in families from the United States (18,66), Canada (186), Germany (111), Italy (103), and the United Kingdom (106). The exact location of the linkage peak is in doubt, however, and there may be two separate peaks, one near the candidate gene described in the following paragraph (18,171,186), and the other about 15 Mb more centromeric (66,103,105).

**108.4.4.1 Candidate Gene Studies.** This locus is the first for which a candidate gene has been named. In 2003, Taipale and coworkers (171) characterized a translocation breakpoint and determined that it disrupted a gene of unknown function they named DYX1C1 (DYX1 candidate 1), later determined to be homologous to mouse Ekn1, a ubiquitin-protein ligase involved in degradation of misfolded proteins (73). Single nucleotide polymorphisms (SNPs) were discovered through gene sequencing and typed in families of dyslexics in Finland. Two SNPs were found to be significantly associated with dyslexia, but subsequent studies of these two SNPs in populations from the United Kingdom and Italy did not replicate these findings (102,148); however, this could be due to separate founder effects in different populations. This supposition has been strengthened by the findings of Wigg and colleagues (186) who typed the original two SNPs as well as additional SNPs in their Canadian families. Linkage disequilibrium was found for an intronic SNP, as well as for the original SNPs; however, in the case of the original SNPs, the opposite alleles were associated with dyslexia, indicating that those particular alleles were neither causal nor in linkage disequilibrium with dyslexia in their population. The mutation in this region could be either in a regulatory region of EKN1 that has not been surveyed or in an adjacent gene. Mutation studies of two phospholipase genes located centromeric to EKN1, phospholipase C beta 2 (PLCB2) and phospholipase A2, group IVB (cytosolic; PLA2G4B), were both negative (105).

#### 108.4.5 DYX2, 6

The strongest and most consistent evidence for linkage with dyslexia has been found for chromosome 6p22.2. First reported in 1991 in a set of extended families selected for apparent autosomal dominant inheritance (162), significant linkage was confirmed in an independent set of nuclear families (13,14). This has been replicated in an independent set of families from the same research group (55) as well as by independent researchers on different samples (39,66,67,178). In those studies, linkage was

seen with all the component processes of single-word reading, phoneme awareness, phonologic coding, and orthographic coding (43,55). Conversely, linkage was not replicated in a Canadian population that assessed phonological coding (38,124) and in a German study that examined a spelling phenotype (111). These differences may be due to population differences or to differences in phenotype definition. In particular, the severity of the phenotype may be a factor in detection of linkage to this locus, since population selection for severity has consistently produced stronger linkage results (13,42,55).

**108.4.5.1 Candidate Gene Studies.** Recent studies in the United States and United Kingdom have narrowed the candidate region to 77–575 kb containing three to five candidate genes (23,47). These include vesicular membrane protein (VMP), doublecortin 2 (DCDC2), TRAF- and TNF receptor-associated protein (TTRAP), KIAA0319, and thioesterase superfamily member 2 (THEM2). Mutations have not been reported in any of these genes, however. Most activity recently has been with two of these genes, KIAA0319 and DCDC2. Significant associations were found with a haplotype of SNPs in the candidate region, with two SNPs in KIAA0319 largely responsible for the disequilibrium. One of these was a cSNP, changing an amino acid in exon 4 (20a). An independent study identified a separate haplotype of three SNPs spanning parts of KIAA0319, TTRAP, and THEM2 with association with dyslexia (47), and subsequent studies by the same group demonstrated that expression of KIAA0319 was reduced in cell lines heterozygous for that haplotype, while TTRAP and THEM2 did not show altered expression (113). There is also modest evidence that KIAA0319L, which is a homolog of KIAA0319, is a candidate gene for SRD. Like KIAA0319, this gene demonstrates expression in the brain, has a transmembrane protein domain, and potential function in neuronal migration (20b). Further, knockdown of KIAA0319 in developing rat brain interfered with neuronal migration to the cortex. Otherwise, the function of the gene is unknown. Similarly, SNPs in and around DCDC2 have been associated with dyslexia, as well as deletions and coding variations in intron 2 (103). The subjects in this study were part of the same US (Colorado) sample in which the initial SNP associations to the region were found (23). The intronic deletions included putative transcription binding sites that could affect expression level. A similar knockdown of DCDC2 function resulted in reduced neuronal migration, as well. A related gene, DCX, is on the X chromosome and produces lissencephaly in hemizygous males and subcortical heterotopia in heterozygous females (OMIM 300121). The latter is reminiscent of the heterotopia seen in autopsied brains of dyslexic individuals (50). Association of SNPs in this gene was also noted in an independent German population (152).

Other genes that have been screened for mutations with negative results include GABA B receptor 1 (GABBR1) (65), myelin oligodendrocyte glycoprotein

(MOG) (160), synaptic RAS-GTPase-activating protein 1 (SYNGAP1) (23a), and secretagogin (SCGN) (Deffenbacher, unpublished thesis).

#### 108.4.6 DYX8, 1p36-p36

Although first suggested by linkage results by Rabin and colleagues (128) that reported an LOD score of 2.33 in the region of the Rh gene, replication was not published until 2001 by Grigorenko and associates (68), who confirmed the linkage in a two-locus analysis, weighting the analysis by the identity by descent for a chromosome 6 haplotype. Recently, the linkage has also been replicated by Tzenova and coworkers (180), without digenic inheritance. Several other genome searches did not identify linkage in this region (35,42,109). Studies with positive linkage results tend to show two peaks of linkage depending on the phenotype and method of analysis, suggesting that there may be two loci spanning a region of about 20 cM. If so, this heterogeneity may have masked linkage in other studies.

**108.4.6.1 Candidate Gene Studies.** Anthoni and colleagues (3b) have refined the 2p12 candidate region in a Finnish and a German population sample, providing evidence for two candidate susceptibility genes, MRPL19 (mitochondrial ribosomal protein 19) and C2ORF3 (chromosome 2 open reading frame 3), for DYX3 locus. These genes are coexpressed in the adult human brain, and are in strong linkage disequilibrium. Moreover, their expression is correlated with DYX1C1, ROBO1, DCDC2 and KIAA0319 genes for SRD, such that individuals with this risk haplotype demonstrate attenuated expression of MRPL19 and C2ORF3 when compared to controls.

#### 108.4.7 DYX3, 2p16-p15

This locus was first identified by Fagerheim and associates (35) in a genome screen of a large Norwegian kindred, and linkage has been replicated in populations from the United Kingdom and Canada (42,123) and two populations from the United States (18,42,46). The linkage region is about 7 cM in size. Linkage to a more centromeric locus, 2p11, has also been identified in families in Finland (82,125), but a large study covering both loci would be needed to be certain that these are separate loci.

**108.4.7.1 Candidate Gene Studies.** Four genes have been screened for mutations with negative results: semaphorin 4F (SEMA4F) and orthodenticle 1 (OTX1) (46), calcineurin B (PPP3R1) (35), and the tachykinin receptor 1 (TACR1) (125). A translocation interrupting the ROBO1 gene in this region was found in one individual with dyslexia, which led the authors to examine the gene in a previously reported Finnish family showing linkage to DYX5 (109). They identified a unique SNP haplotype in ROBO1 with strong association to the dyslexia in that family. Expression of the gene was reduced in the mRNA of individuals who were heterozygous for the associated

haplotype. The haplotype was not found in an independent sample of 96 dyslexic individuals, however (71). The *Drosophila* homolog of this gene, robo, and the mouse homolog, Robo1, are both involved with midline neuronal migration (3a).

#### 108.4.8 DYX5, 3p12-q13

This linkage has been reported in three separate populations (42,109), but the critical region is quite large, spanning almost 25 cM.

**108.4.8.1 Candidate Gene Studies.** Two genes have been screened with negative results: the 5-hydroxytryptamine receptor 1F (HHT1F) and the dopamine receptor D3 (DRD3) (109).

#### 108.4.9 DYX6, 18p11.2

In genome screens of three independent populations (one from the United States and two from the United Kingdom), this locus provided the strongest evidence for linkage in all three (42). Linkage was not replicated by Chapman and colleagues (18), however. The linkage was reevaluated in one of the UK populations using a multivariate linkage analysis method (103), with a resulting decrease in the level of significance from  $p = 0.00001$  for single-word reading to  $p = 0.0011$  for all phenotypes simultaneously. This suggests that the significance level obtained in the original genome screen may be an overestimate.

**108.4.9.1 Candidate Gene Studies.** No gene mutation studies have been reported.

#### 108.4.10 DYX9, Xq27.3

Linkage to Xq27.3 has been reported in one large family in Holland (22), but was not replicated in a small set of sibling pairs that they analyzed. Linkage to this region is also mentioned in the report of genome screens by Fisher and colleagues (42).

**108.4.10.1 Candidate Gene Studies.** Four genes were screened in the linked family reported by de Kovel and colleagues (22): fragile X mental retardation 1 (FMR1), Cxorf1, DKFZp574M2010, and KIAA1854, with no mutations detected in any of the genes.

Linkage studies have also addressed phenotypic issues by comparing different phenotypic measures to see if there were differences in the linkage results. Grigorenko and associates (67) examined phonological and orthographic measures, as well as more global single-word reading measures. Linkage to chromosome 6p was most significant for a measure of phonemic awareness, although other phonologic measures were also significant. Conversely, linkage to chromosome 15q was significant for the single-word reading measure, leading them to conclude that the two genes influenced different reading processes. However, studies by Fisher and colleagues (43) and Gayán and associates (55) did not find similar

results for the chromosome 6p linkage; while phonologic awareness measures were important, significant results were also found for the other phonologic measures as well as orthographic coding measures, suggesting that the locus had a more general influence on reading ability. Subsequent analysis by Grigorenko and coworkers (67) with a larger sample confirmed the linkage to 6p, but the phenotype was expanded to include other phonologic measures and vocabulary. Thus, linkage to chromosome 6 does not support the assignment of a particular cognitive process to a specific gene, nor does it support dissociation between phonologic and orthographic abilities. The same pattern has been seen for other loci (42,46). It may be that, at this level of phenotypic analysis, these highly correlated phenotypes should not be expected to have separate, modular genetic influences (117). Refinements of the phenotypes along with larger sample sizes may indicate that some loci do have greater effects on one type of measure than another (187).

#### 108.4.11 New Candidate Loci

Using an event-related potential correlate of speech perception that has been shown to be impaired in dyslexic individuals, Roeske and colleagues (136) found a significant association with SLC2A3 on 12p13.3. They replicated this finding in a second independent sample of children with SRD. SLC2A3 facilitates glucose transport in neurons and is thought to lead to glucose deficits in children with SRD.

#### 108.4.12 Missing Heritability

Although it is clear that there is a strong genetic component underlying SRD, the proportion of variance accounted for by candidate loci does not add up to heritability estimates for SRD. This “missing heritability” problem, of course, is not specific to this disorder and is common to all studies of complex behavioral disorders (101). There are a number of hypothesis that suggest why this effect exists. Most notably, prominent scientists, such as Eric Lander, have suggested that epistasis (suppression of a gene by another gene) plays a major role when considered alongside current methodologies such as genome-wide association studies, which are underpowered to find gene–gene interactions.

DNA methylation, which is the addition of a methyl group to a stretch of DNA that often results in the silencing of the portion of DNA sequence, is the most stable form of epistasis in mammalian genomes. Recent studies of DNA methylation have shown that it is a common occurrence in the human genome (for a review see Reference (103)). The effects can be allele specific and quantitative or heterogeneous. In other words, the effects of methylation may not be evenly distributed across both alleles; they may differ across tissues and individuals, and 10% may be non-cis (acting from a different molecule) such as parental

origin. These methylation effects, which demonstrate that noncoding sequences can have functional effects, then reduce the observed relationships between genes and behavior when not accounted for directly. Another reason why some of the genetic variance may be unaccounted for could be shared prenatal effects or the “maternal effect” that can be transmitted to siblings and appear genetic when in fact, it is environmental in origin (183).

#### 108.4.13 Summary of Genetic Studies

The evidence so far supports the idea that both normal reading and SRD can be influenced by genetic factors. Segregation analyses support the hypothesis that a limited number of loci are involved, with at least some having a major gene effect, and linkage analyses have identified at least seven candidate loci. Some of the ambiguity in results or the lack of findings may reflect the fact that both segregation and linkage analysis are dependent on the definition of the phenotype. As the phenotypes are more closely defined and new techniques for analysis of quantitative trait loci are developed, the mode of inheritance and the role of individual loci should become clearer.

### 108.5 COMORBIDITY

SRD is frequently comorbid with other language disabilities, including specific language impairment (SLI), and speech sound disorder (SSD) (phonologic disorder). Comorbidity for two or more disorders may have a number of causes: they may be two separate but common disorders with different causes and independent segregation, complications of one disorder may produce a phenocopy of the other disorder, or the two disorders may be pleiotropic effects of the same underlying gene. There is evidence supporting all three of these possibilities.

#### 108.5.1 Speech Sound Disorder and Specific Reading Disability

SSD is a developmental disorder of articulation, specifically the production of developmentally inappropriate errors in pronunciation that interfere with the ability to produce understandable speech. SSD includes problems with articulatory output (deficits in phonetic structure due to poor motor skills) and phonological processes (failure to learn the pattern of sounds in a particular language) ([www.ASHA.org](http://www.ASHA.org)). While the etiology of some SSDs are known such as hearing loss, it is diagnosed in young children, and both prospective and retrospective studies have indicated that many of these children later develop reading disability (see Raitano and colleagues (129)). The prevalence of SSD at 3 years of age has been shown to be 16%; however, only 3.8% of children continue to present a speech delay at 6 years of age (10). This estimate does not include children who have speech/language problems secondary to other conditions.

Susceptibility to SSD has been shown to have a strong genetic influence (6a). For example, familial segregation has been demonstrated in 20–40% of first-degree relatives of children with SSD (93). Moreover, segregation analyses have also confirmed familial aggregation of SSD and supported both a major gene and polygenic modes of transmission of the disorder (6a,86,148). Stein and associates (167) ascertained families with children with SSD and found linkage with markers in the centromeric region of chromosome 3, within the region of linkage of SRD. Similarly, Smith and colleagues (163) presented evidence for linkage of SSD with the SRD regions of 1p36, 6p22.2, and 15q21. These results suggest that shared developmental deficits in phonological representation or retrieval affect both disorders.

### 108.5.2 Specific Language Impairment and Specific Reading Disability

Like SRD, SLI is primarily defined by exclusionary rather than inclusionary criteria. In general, a person with SLI exhibits unexplained deficits in receptive and/or expressive language skills, without any evidence of deficits in nonverbal IQ, neurologic impairment, or environmental or emotional problems that could explain the language delays. These deficits can be seen in some or all five global language domains: phonology (analysis of the sounds of language; articulation), morphology (e.g. word formation and grammar; prefixes, suffixes, tense marking), syntax (word order), semantics (word meaning), and pragmatics (the practical use of language to convey purpose and emotion) (92,172,176). Thus, children with this disorder have trouble with the formation and learning of the rules of language and their appropriate application more than with articulation and phonology (113). Given the wide range of SLI phenotypes, research in this area is difficult to consolidate.

There are several major hypotheses regarding the causes of SLI, and some show overlap with the hypothesized causes of SRD. For example, difficulty in auditory processing (e.g. References (174,175)) or in defective cognitive/representational abilities (80,81) has been proposed. Studies of auditory perception have focused on language stimuli, with apparent problems in the perception of artificially generated, very brief auditory signals (174,175). The deficits were corrected when the signal was prolonged. The work of Tallal and colleagues (e.g. Reference (134)) also found deficits in discriminating brief sounds, similar in length to stop consonants, along with poorer perception of degraded speech and difficulty processing rapidly presented auditory stimuli. These findings were replicated by Wright and associates (191) with psychophysical tests that showed perceptual deficits for brief tones. These theories have attracted a great deal of attention lately, in part due to their application to treatment/remediation techniques (see Reference (104) and later in this chapter).

Although these results are intriguing and provide some parallels to the visual and auditory evoked response studies reviewed previously for SRD, others have argued that the described deficits in auditory perception are too limited and are not sufficient to account for the full range of linguistic problems typically found in SLI children (8,64,91,92,185). In addition, Bishop and colleagues (7) used a twin design and determined that the auditory perception test used did not show significant heritability, whereas phonological measures did show high estimates of heritability. A shared environment appeared to be more significant in accounting for variation in performance on the auditory perception tests. It is still possible, however, that the auditory perception deficits are an important clue to an underlying neurologic abnormality.

There are also suggestions of similarity in pathogenesis between SLI and SRD. The deficit in the processing of rapid auditory stimuli proposed by Tallal and Stark (174) and Tallal and colleagues (175) could result from the same mechanism underlying the deficits in fast transient visual stimuli studied in dyslexics, perhaps also mediated by magnocells. Accordingly, Tallal and associates (173) expanded their hypothesis by proposing that problems in perception of any rapidly presented stimuli result in a cascading disruption of intersensory integration processes, including phonologic processing. Liberman (95) cautioned about taking the parallels between reading and speech disorders too far, particularly in attributing speech problems solely to difficulties in phonologic perception or awareness. He maintained that speech perception is not the same as reading in that speech deals with more than just phonology; one does not need to learn the underlying segmentation to understand speech, and oral motor feedback is also an important consideration. Thus, rather than being the primary deficit for SLI (or SRD), the difficulty in processing rapid stimuli may be correlated with the underlying deficit for SLI, which may be closely related to, but not exactly the same as, the underlying deficit in SRD.

While these differences would suggest that SLI and SRD show limited etiological similarity despite their comorbidity, linkage studies suggest that the etiologic overlap that exists may be small. For example, a genome screen of SLI phenotypes did not show localization to any known SRD loci (158), but further studies of a candidate locus on 16q that was identified in this screen showed that SRD phenotypes also linked to this region (159). In another study of families selected for SLI, Bartlett and colleagues (4) found linkage of SRD phenotypes (but not SLI phenotypes) to chromosome 13q21. Neither of these regions was identified in genome screens of SRD (42).

### 108.6 RECURRENCE RISKS

Certainly, there is great value in identifying children at high risk for SRD so that effective remediation is not delayed. However, since it is very likely that there is

etiologic heterogeneity in reading disability, it is impossible to give precise recurrence risks in individual cases. In some families, the inheritance pattern may suggest a dominant gene with high penetrance, while other children with SRD may be sporadic cases with low recurrence risks (see Reference (63) for illustration of risk estimate fluctuation as a function of major gene or polygenic influence on SRD). While a strongly positive family history would indicate a higher recurrence risk, regardless of the mode of inheritance, the exact magnitude of the risk can only be estimated. Empirical risk figures can be provided to the family, however, and the results of the segregation analysis by Pennington and associates (120) would suggest close to a 50% recurrence risk for male siblings, and 28% for female siblings of a dyslexic child.

Other types of studies have produced somewhat similar figures. Gilger and colleagues (63) used the data from three family studies to calculate the chance that an affected parent would have an affected child. Using their most unbiased data set and assuming 3.5:1 sex ratio for SRD, sons of an affected father had a 39–58% probability of being affected, and daughters had a 19–32% risk. Sons of an affected mother had a 30–48% probability of being affected, slightly less than if the father was affected, but her daughters had a comparable risk of 18–32%. (The two risk figures reflect estimated population base rates of 5 or 10%, respectively.) If a 1:1 sex ratio was assumed, the risks for daughters went up to 35–50% regardless of which parent was affected, and risks for sons went down to 29–45% with an affected father and 20–36% with an affected mother. Whether these sex differences are genetic or environmental is unclear; however, while these data may appear consistent with a multifactorial/threshold trait, the segregation analysis and linkage analysis results would suggest that the number of loci involved cannot be great, and that modification of a major QTL must also be considered.

It has also been suggested that the risk to offspring varies according to whether the parent has compensated for their childhood SRD (60). For example, if one parent had SRD that began in childhood and their spouse was unaffected, 60% of the children were SRD, but if the parent had compensated (i.e. was affected with SRD in childhood but not in adulthood), only 30% of the children were affected, and if both parents had never had signs of SRD, 20% of the children were affected. The latter figure of 20% is somewhat greater than the generally accepted population frequency of 5–10% as one might have expected, but this may be due to the truncated selection of the families in the study; that is, all the families had at least one affected child, the proband, at the outset and therefore were more heavily loaded for SRD than the population at large. This type of family study did not permit separation of genetic and environmental effects, so the mechanism of the compensation effect on recurrence could not be determined. In addition, it is possible that this effect is confounded somewhat by the sex effect

observed by Gilger and coworkers (63), since compensation is more common in females (see also Pennington and associates (120)). In sum, the studies we have reviewed indicate some fluctuation in the recurrence risk based on characteristics of the affected parent. These findings must be replicated and investigated further to determine whether sex and/or severity of the affected parent have an effect on transmission. If so, the mechanism of such an effect may reveal important aspects of the mode of inheritance of SRD.

## 108.7 DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of dyslexia requires a convergence of data from three domains: the child's developmental and school histories, qualitative aspects of the child's reading and spelling performance, and quantitative test scores. These are all covered in greater detail elsewhere by Pennington (116) and Fletcher and associates (45). Briefly, the preschool developmental history is often essentially normal, although there may be mild speech delays and articulation difficulty. Problems with reading and spelling are usually noticed by first or second grade, with phonetic errors in reading and spelling. To confirm the diagnosis, psychometric testing needs to be done by a well-trained child clinical or educational psychologist who is familiar with dyslexia. At a minimum, this testing should include an IQ test, such as the WISC III, and tests of academic achievement, such as the Woodcock–Johnson, Revised, the Gray Oral Reading Test-Revised (GORT-R), and the spelling subtest of the Wide Range Achievement Test-Revised (WRAT-R). It is important that the academic battery include measures of spelling, nonword reading, and reading speed and fluency for paragraphs (e.g. the GORT-R), since these areas are particularly difficult for dyslexic individuals. Some dyslexics, especially older or brighter ones, may perform normally on untimed measures of single-word reading accuracy or reading comprehension, which can lead to a false-negative diagnosis if these other, more sensitive measures are not used. Of course, a variety of different tests are available for the assessment of the essential reading-related domains and an interdisciplinary diagnostic team is suggested and becoming common practice. Nonetheless, research is coalescing toward relatively reliable measures of early identification and formal and simple instruments have been developed that are becoming handy tools in this endeavor (69,166). (See also the Web site <http://dibels.uoregon.edu/>.)

## 108.8 TREATMENT

Treatment of dyslexia can be viewed from two perspectives: remediation and compensation. Remediation involves intensive training of the weak phonologic skills, since it is impossible to completely bypass phonics

in learning to read, particularly in English, but the best method to treat reading disability is debated.

There are several therapies for which scientific support is lacking or further research is required (Silver (157); Creaghead (21) and accompanying articles). Among these are tinted lenses, visual training, patterning, auditory processing training, fast-for-word (104), and various nutritional additives or adjustments. At this time, multisensory approaches such as Orton-Gillingham and systematic training on letter-to-sound correspondences are favored by the International Dyslexia Association (IDA) and many other experts (see IDA address at end of chapter and Hall and Moats (69)).

Compensation for SRD involves strategies that both the child and the educators can use to work around some of the problems posed by the disorder. For instance, reduced time pressure, marking but not penalizing for spelling errors, not being asked to read aloud in class, and possible waiver of foreign language requirements, are all things that the school environment can provide to help dyslexic children perform to their greatest potential. Things the child can do themselves include use of spell checkers (including handheld models), calculators to check computation, and tape recorders or other aids for note taking. Dyslexia can easily lead to secondary emotional problems, and these must be monitored carefully by both teachers and parents.

There is growing recognition that many of the common practices in the field of education today are based more on opinion or tradition than they are on scientifically sound evaluations of their efficacy (No Child Left Behind, Reading First, PL 107-110, 2002; (71,164). This is particularly true in the field of academic remediation for learning disabilities, where the types of help available to children are typically limited, conventional, and applied in a one-size-fits-all manner (71,177). The mantra of scientifically based treatments or interventions (SBI) is being echoed across the country, in part due to recent federal mandates (e.g. PL 107-110, 2002; IDEA, 2004). Public and private schools, clinics, and the like, are being asked to “step up to the plate” and make responsible efforts toward validating their treatment programs and/or developing treatment programs that have data-based validity.

The essentials of scientifically based interventions (SBI) for dyslexia can be found in several documents (see [www.whatworks.ed.gov](http://www.whatworks.ed.gov); Institute for Educational Sciences (IES), US Department of Education). Among the key requirements for evidence of efficacy to be considered “strong” and scientifically valid are that the intervention be tested using randomized (or other appropriate) types of controlled trials and that the intervention be shown to be effective in more than one setting and by more than one independent investigator. It is noteworthy that basic pre- and post tests and studies do not provide “strong” evidence of efficacy or even “likely” evidence and that such studies can produce misleading results (IES).

Literacy is one of the best studied domains of academic abilities. Reading teaching practices and reading remediation for the learning disabled or dyslexic individual have benefited from a great deal of basic research, although there is still much to be learned (135,170). Research has in fact identified the basic cognitive component areas or processes needed for the development of reading skills (30,132,164). These processes or abilities include phonemic awareness, phonics, fluency, vocabulary, and comprehension strategies, each of which is essential for the accurate and fluent identification of words and the ultimate construction of meaning (comprehension).

Researchers are beginning to use this general model of component skills as a framework for assessing the adequacy and potential effectiveness of specific reading teaching programs. This is particularly true in the case of programs for reading remediation where at the first step of validation, programs are examined for their adherence to training and development of the several componential skills identified previously. There are a number of reading remediation programs available, none of which meet the criteria to be an SBI, although many programs are now being studied with proper controls and replications as required by IES.

In summary, there is both a moral and legal obligation to develop and provide SBIs. There is a plethora of reading programs for dyslexics and nondyslexics alike that make far-reaching claims that have little or no support using objective data. Many of these programs have face validity, but upon closer scrutiny they do not train in any coherent way the several basic componential skills essential to reading development. Some programs, however, do appear to have support from a theoretical view in that they train in areas related to the componential skills and some programs do have at least preliminary data supportive of their efficacy. Among such programs are the several varieties of reading remediation based on the Orton-Gillingham multisensory approach (1,73). Sometimes referred to as multisensory-structured language (MSL) methodologies, this family of programs are typically intense, incremental, cumulative, explicit, and systematic, and address in some way the essential componential skills identified in the National Reading Panel report (30,132,164).

Significant support for families and dyslexic individuals can come from organizations such as the International Dyslexia Association (formerly the Orton Dyslexia Society), which has branches in many states. The national headquarters can be reached at

## Biographies

**Name:** Angela Friend

**Position/Title:** Research Associate

**Affiliation/Institution/Location:** University of Denver

**Discipline(s):** Cognitive Psychology, Behavioral Genetics

**Background-Training-Experience:** Angela Friend's background includes an MA and PhD in Cognitive Psychology with a specialty in Behavioral Genetics. Her training includes genetic methodology on twin and family data, structural equation modeling, multivariate statistics, item response theory, bioinformatics and genomics, and quantitative trait loci analysis. Her research has focused on understanding the etiology of component processes related to reading disability and, more recently, on gene by environment (GxE) interactions at the extreme tails of the distribution of reading ability through the application of quantitative behavioral genetic methodology in data from twins. Her current projects include studying the extent to which language impairment and other cognitive risk factors mediate the relationship between speech sound disorder and dyslexia at the phenotypic and genetic levels of analysis, specifically, how language impairment may mediate the relationship between speech sound disorder and dyslexia.

**Name:** Shelley D Smith

**Position/Title:** Professor of Pediatrics

**Affiliation/Institution/Location:** University of Nebraska

**Discipline(s):** Board Certified Medical Geneticist

**Background-Training-Experience:** Shelley Smith is a medical geneticist who conducted the first genetic linkage analysis of reading disability for her doctoral dissertation in 1978. In 1986, she edited a research monograph entitled Genetics and Learning Disabilities. Her collaboration with CLDRC investigators led to the identification of the region on chromosome 6 containing the candidate genes DCDC2 and KIAA0319, the most replicated of all the reading disability candidate genes. She is Professor of Pediatrics, Departmental Section Chief of Molecular Genetics, and Chair of the Developmental Neuroscience Department in the Munroe Meyer Institute for Genetics and Rehabilitative Medicine at the University of Nebraska Medical Center. She has been involved in gene identification studies for deafness disorders and learning disabilities, including separate R01s in collaboration with Dr Pennington, which study families with phonological disorder, and with Dr Mabel Rice at the University of Kansas focusing on specific language impairment. She is currently PI of an NIH/NCRR Center for Biomedical Research Excellence (COBRE) on the Molecular Biology of Neurosensory Systems, which supports three research core facilities and four research projects in studies of the development of auditory and visual systems. She is certified by the American Board of Medical Genetics as a PhD Medical Geneticist and provides clinical services in the neurosensory genetics clinic at Boys Town National Research Hospital in Omaha.

Name: **Jeffrey W Gilger**

Position/Title: Professor

Affiliation/Institution/Location: Purdue University

Discipline(s): Developmental Psychology, Behavioral Genetics

**Background-Training-Experience:** Jeff Gilger's background includes an MS and certification in Clinical Child/School Psychology, and an MA and PhD in Developmental Psychology with a specialty in Behavioral Genetics. His scholarship is inherently multidisciplinary spanning the clinical, educational and neuroscience disciplines. Dr Gilger's teaching and research has tended to focus on normal and abnormal neuropsychological development, genetics, and the etiology of learning-language disorders, especially dyslexia. Current research projects include the neurology/genetics of the gifted-learning disabled individual and the effects of subclinical brain damage in adolescents, among others.

Name: **Bruce F Pennington**

Position/Title: John Evans Professor of Psychology

Affiliation/Institution/Location: University of Denver

Discipline(s): Developmental Psychology

**Background-Training-Experience:** Bruce F Pennington, PhD, is a developmental neuropsychologist who has earned an international reputation for his research on dyslexia, ADHD, and autism. He is particularly interested in using genetic and neuropsychological methods to understand comorbidity among disorders, such as the comorbidity between dyslexia and ADHD. He has been the primary research mentor for 35 doctoral and postdoctoral students, many of whom are now pursuing their own research on developmental disabilities. He heads the Developmental Cognitive Neuroscience program. His honors include Research Scientist, MERIT, and Fogarty awards from the National Institutes of Health; the Samuel T Orton Award from the International Dyslexia Association; and the Emanuel Miller Lecture from the British Child Psychology and Psychiatric Association. He is also a Fellow of AAAS.

He recently published *The Development of Psychopathology: Nature and Nurture*. (Guilford Press, 2002). His first book, *Diagnosing Learning Disorders* (Guilford Press, 1991), has now been revised and the second edition was published in 2008. It emphasizes a close relationship between research and practice. In addition to being a researcher and research mentor, he is also a child clinical neuropsychologist, and has been active in clinical practice and training throughout his career.

## Attention-Deficit/Hyperactivity Disorder

*Stephen V Faraone*

Medical Genetics Research Center and Department of Psychiatry and Behavioral Sciences, SUNY Upstate Medical University, Syracuse, NY, USA

*Alysa E Doyle*

The Center for Human Genetics Research and Department of Psychiatry, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA

ADHD is a childhood-onset behavioral disorder characterized by excessive inattention and/or hyperactivity and impulsivity. It is common in populations across the globe. A recent paper reported a worldwide, pooled prevalence of approximately 5.3% (1); however, estimates are often as high as 10% (2). Although a subsample of affected individuals remit, the majority of patients continue to exhibit impairing symptoms into adulthood, and there is a strong association between the disorder and academic and career underachievement in addition to conduct problems and substance abuse (3,4). Thus, given its prevalence, the impact of this condition on society is vast in terms of financial cost, stress to families, and disruption in schools and the workplace.

The disorder was first described in detail in the late 1950s as “hyperkinetic or overactive behavior,” and subsequent labels such as “minimal brain dysfunction” and “hyperactive child syndrome” continued to emphasize hyperactivity as the essential component of the disorder. With the advent of DSM-III came the distinction between attention deficit disorder with (ADHD) and without hyperactivity (ADD). Owing to debates about whether inattention without hyperactivity was a clinically valid syndrome, DSM-III-R combined the two subtypes into a single entity. The publication of DSM-IV in 1994, however, marked a return to subtypes—including a primarily inattentive subtype, a primarily hyperactive/impulsive subtype and a third that mixes both symptom dimensions. At the time of this writing, changes are proposed to DSM-V, including the possible return to a single category ([www.dsmV.org](http://www.dsmV.org)), because of the instability of the different subtypes over time and the lack of strong neurobiological evidence for their distinction.

Since the mid 1960s, researchers have used behavioral genetic designs to examine the etiology of this condition. Despite a changing nosology, estimates of familiarity and heritability have been quite consistent over time (5) and, together, family twin and adoption studies indicate definitively that the development of ADHD is influenced to a large extent by genes. Nonetheless, these studies also support heterogeneity of the phenotype, and the more recent molecular genetics literature suggests that ADHD is complex and multifactorial.

### 109.1 BEHAVIORAL GENETICS

#### 109.1.1 Family Studies

There is substantial evidence that ADHD runs in families. Early studies of hyperactivity and subsequent studies of each recent variation of the DSM ADHD diagnosis agree that the parents of ADHD children have a two- to eightfold increase in the risk for disorder (5). In addition to confirming the transmission of ADHD, family data provided the initial evidence for the validity of the diagnosis in adults as well as particularly high rates of ADHD in their relatives, e.g. Faraone et al. (6), suggesting a higher genetic loading in persistent cases.

Our group confirmed and extended these family study findings using more definitive double-blind, case-control studies of large samples of boys (7) and girls (8) and adults (6) with DSM-III-R and DSM-IV ADHD. In addition, both male and female probands and their relatives had higher rates of comorbid conditions such as conduct, mood and anxiety disorders than respective controls. Further attention to these other psychiatric disorders in

family studies suggests genetic heterogeneity and shared risk with some but not all of the disorder's common comorbidities. Overall, independent samples suggest that (1) ADHD and major depression share common familial vulnerabilities (9); (2) ADHD children with conduct (10) and bipolar (11) disorders might be a distinct familial subtype of ADHD; and (3) ADHD is familially independent from anxiety disorders (12). Thus, stratification by conduct and bipolar disorders may cleave the universe of ADHD children into more familially homogeneous subgroups. In contrast, major depression may be a nonspecific manifestation of different ADHD forms.

### 109.1.2 Adoption Studies

Whereas parents can confer a disease risk to their biological children via both biological and environmental pathways, parents of adoptive children only confer risk via an environmental pathway. Thus, examining both the adoptive and the biological relatives of ADHD probands helps to disentangle genetic and environmental sources of familial transmission. Two early studies found that the adoptive relatives of ADHD children were less likely to have ADHD or associated disorders than the biological relatives of ADHD children (13,14). Biological relatives of ADHD children also performed more poorly on standardized measures of attention than did adoptive relatives of ADHD children (15). Consistent with these earlier studies, a more recent adoption study that examined DSM-III-R ADHD found higher rates of the disorder in the biological parents of ADHD children compared with adoptive parents (16). Conclusions from these studies must be considered in light of the limitation that the adoptive and biological relatives of the same children were not compared. Nonetheless, these data support the twin data, described below, to highlight the role of genes in the etiology of the disorder.

### 109.1.3 Twin Studies

Twin studies rely on the assumption that reared-together identical (or monozygotic [MZ]) and fraternal (or dizygotic [DZ]) twins share equal amounts of environmental influences but differ in their genetic similarity. While MZ twins share all of their genes, DZ twins share no more genes that siblings would, on average 50%. According to the logic of the twin design, the finding that MZ twin pairs are more likely to have the same disorder than are DZ twin pairs shows that genes play a causal role in the disorder.

When examined independently and together, twin studies of ADHD suggest that the heritability of the disorder is quite high. Our group estimated a heritability of 0.76 across studies in the literature (5), which places ADHD among the most heritable of psychiatric conditions. Yet these data also suggest that approximately a fourth of the variance in the population is due to

nongenetic factors, particularly factors that relate to the unique environment of individuals rather than the environment shared among family members (17). Specific nongenetic influences that have shown repeated association with ADHD in the literature include low birth weight (18) as well as maternal smoking and alcohol use during pregnancy (19). Recent data suggests that exposure to lead and environmental toxins including PCBs should be considered as well (17,20). How these environmental factors may interact with genetic vulnerability is an important topic for future studies.

Twin studies have also examined the genetic overlap between the two ADHD symptom dimensions, inattention and hyperactivity-impulsivity. On the basis of 288 male twin pairs, data from the Minnesota Twin Family Study (21) found that common genes contribute to both symptom dimensions, but the bivariate heritability was substantially larger when based on mothers' (0.86) as opposed to teachers' reports (0.33). Data from larger, recent studies (22,23) continue to support substantial genetic overlap of the dimensions as well; however, data from these projects further clarify the existence of a significant proportion of nonoverlapping genetic influences on each dimension.

Twin designs additionally provide a means of examining the genetic contribution to the comorbidity of ADHD and other disorders. Although it has been suggested that ADHD and reading disability were genetically independent (24), several recent reports (23,25,26) support mutual genetic influences on measures of reading and inattention symptoms, but low to negligible overlap between reading and hyperactive/impulsive symptoms. Overlap between conduct problems and ADHD has also been explored extensively. Nadder et al. (27) found that 50% of the correlation between the ADHD and CD was due to shared genes. These findings are consistent with those from our own family work (10) showing that ADHD and conduct disorder tend to cosegregate in relatives of ADHD probands. More recent twin studies have extended this investigation beyond DSM categories to document a more general, heritable liability for externalizing psychopathology factor that cuts across diagnoses of ADHD, CD and ODD and may in part account for their comorbidity (28,29). Finally, twin studies have documented genetic overlap between ADHD and the autism spectrum, in terms of specific diagnostic categories autistic traits that have been examined in nonclinical samples (30).

## 109.2 MOLECULAR GENETICS

### 109.2.1 Candidate Gene Studies

Biological candidate genes for ADHD have predominantly been related to the catecholamine system. Our 2005 meta-analysis (5) showed small but statistically significant pooled odds ratios, ranging from 1.1 to 1.5,

for five genes related to dopamine (DA) and/or its neurotransmission, including the dopamine (DA) transporter (*SLC6A3*), the DA 4 receptor gene (*DRD4*), synaptosomal associated protein 25 (*SNAP-25*), the DA 5 receptor gene (*DRD5*), and the gene coding for dopamine beta-hydroxylase (*DBH*). An updated meta-analysis (31) confirmed the association between these genes, with similar effect sizes, and also found association between the serotonin transporter (*5HTT*) and the serotonin receptor 1B (*HTR1B*). Owing to space constraints, we refer readers to these meta-analyses for further details; however, we briefly discuss three of what are arguably the most compelling candidate genes to be investigated.

*SLC6A3* was the first candidate gene to be examined for ADHD (32), and recent studies strongly support its involvement in the pathophysiology of the condition. The solute carrier transporter protein coded by the gene is integral to the reuptake of synaptic DA, and methylphenidate achieves at least part of its therapeutic effects by blocking its action (33). Increased transporter density in the striatum has been documented in several studies of adults with ADHD versus controls (34). *SLC6A3* also lies in a region on 5p13 that has been highlighted in genome-wide linkage studies of ADHD (described below) (35). A variable number tandem repeat (VNTR) in the 3' untranslated region (UTR) of the gene has been the primary focus of molecular genetic studies because of some evidence of functionality (36). Our 2005 meta-analysis (5) of 14 studies showed a small but statistically significant pooled odds ratio for this polymorphism (1.13; 95% CI 1.03–1.24) with the 10-repeat (10R) allele conferring increased risk for the disorder. An updated meta-analysis found a comparable, modestly but significantly increased risk for the disorder with the 10R allele (31) as well as evidence for heterogeneity of the effect size across studies. Recent reviews (31,37) agree that more attention to other markers in this gene is warranted. One other VNTR in intron 8 and three additional SNPs (in exon 8 and the 3' UTR region) have been examined with enough frequency to be included in Gizer et al.'s recent meta-analysis (31), with only the other VNTR showing significant association (OR = 1.19, CI = 1.05–1.34). Other recent investigations also suggest that environmental risk factors including maternal alcohol use and smoking during pregnancy may represent mediators of the association with *SLC6A3* variants and the disorder (38,39).

*DRD4* codes for a G-protein-coupled catecholamine receptor that is prevalent in frontal-subcortical networks implicated in ADHD by neuroimaging and neuropsychological studies (40). Authors of a *DRD4* knockout mouse study concluded that the gene was implicated in a variety of relevant phenotypes including activity level, sensitivity to methylphenidate and nigrostriatal DA neuronal activity (41). Researchers have focused on a polymorphic 48-bp repeat in exon III because in vitro studies have shown that the 7-repeat allele produces a blunted response to dopamine (42,43). The significant

association of the 7R allele with the disorder was demonstrated in our 2005 meta-analysis (5), with an odds ratio for case-control studies of 1.9 (95% CI 1.4–2.2), and for family-based studies of 1.4 (95% CI 1.1–1.6). Gizer et al.'s (31) update found a comparable effect (OR = 1.3, CI = 1.16–1.39) as well as significant heterogeneity across studies. Similar to *SLC6A3*, more work is needed to investigate other markers in the gene. Only an insertion/deletion in the promoter region and an SNP thought to influence promoter activity (rs1800955), have been examined with frequency, and Gizer et al. found a significant, though modest, association with its T allele (OR = 1.21, CI = 1.04–1.41).

*SNAP-25* encodes a plasma membrane protein involved in neurotransmitter release, axon growth and synaptic plasticity (44). The *Coloboma* mouse, considered an animal model of ADHD, is characterized by a hemizygous, 2-cM deletion on chromosome 2q that includes this gene. Such mice display spontaneous hyperactivity, delays in complex motor abilities, deficits in hippocampal physiology, and deficits in Ca<sup>2+</sup>-dependent striatal dopamine release (45). Previous studies have tested several markers within *SNAP-25*. Our prior meta-analysis showed a modest but significant effect (1.19 [CI 1.03–1.38]) in family-based studies for the T allele of rs3746544, located in the 3' UTR. Updated meta-analyses (31,46) examined this as well as a handful of other markers in the gene that have been explored in multiple studies. Both found the same allele in rs3746544 to be associated with ADHD (both OR = 1.15 [CI 1.01–1.31]). Because this SNP is not functional, more work is needed to determine its role in risk for the disorder or whether it is in linkage disequilibrium (LD) with a different risk variant.

In their recent review, Barr and Misener (37) note the strong support for the involvement of these and other DA-related genes in ADHD, but highlight gaps that must be filled by the next generation of studies. First, true risk alleles remain unclear because a few studies have examined allelic variation across entire genes. Second, the mechanism by which specific variants confer risk for the disorder is yet to be determined. Thus there is considerable interest in examining the association of ADHD-related candidate genes with more direct indices of the putative neurobiology of the disorder. Early work examining the association of candidate genes including *DRD4* and *SLC6A3* with neuroimaging and neurocognitive phenotypes has begun to reveal a relationship with prefrontal striatal neural networks relevant to ADHD (47).

## 109.2.2 Genome-Wide Linkage

Genome-wide linkage scans have aimed to identify chromosomal regions that harbor genes for ADHD. This approach examines many DNA markers across the genome to determine if particular markers are co-inherited with the disorder of interest. Although the markers in question may not themselves be functional, excess

sharing of alleles in affected family members suggests that the marker is in close enough proximity to true risk variant as not to be disrupted by meiosis. Regions identified in these studies can then be examined in more detail using additional markers.

The majority of genome-wide linkage studies of ADHD have targeted affected youth. The first of these, which examined 126 affected sib-pairs from the United States, found three regions showing some evidence of linkage (LOD scores  $>1.5$ ): 5p12, 10q26, 12q23, and 16p13 (48). An expanded sample of 203 families found stronger evidence for the 16p13 region, previously implicated in autism, with a maximum LOD score of 4 (49). A study of 164 Dutch affected sib-pairs also identified a peak previously noted in autism, at 15q15, with a peak LOD score of 3.5 (50). Two other peaks, at 7p13 and 9q33, yielded LOD scores of 3.0 and 2.1, respectively. Pooled analyses of these two studies (49,50) suggest that the lack of consistent findings is a reflection of between-population heterogeneity (51) and revealed a region on 5p13 that may reflect a common risk locus. A study of 155 sib-pairs from Germany (52) also reported a maximum LOD score of 2.59 for this distal arm of 5p at 17cM, providing further support for a potential ADHD locus in this region. They also reported nominal evidence for linkage to chromosomes 6q, 7p, 9q, 11q, 12q and 17p, which had been identified in previous scans. A genome-wide scan of families from an isolated community in Columbia implicated 8q12, 11q23, 4q13, 17p11, 12q23, and 8p23 (53).

More recent linkage studies have used an SNP-based panel of markers with arguably finer resolution than previous studies. With such a platform, our group at Massachusetts General Hospital found no regions of significant or suggestive linkage in 217 families when targeting the ADHD diagnosis and quantitative symptom (54); however, in this same sample, we identified a potential QTL at the suggestive level on 3q13 using a multivariate linkage strategy combining neurocognitive traits and ADHD symptoms (55). Specifically, all of the neurocognitive traits and inattentive but not hyperactive/impulsive symptoms showed linkage to this region, which has been implicated in autism (ref) and in dyslexia, which, as reviewed above, shares genetic risk with ADHD inattention symptoms. On the basis of the ADHD phenotype alone, Asherson et al. (56) and the International Multi Centre ADHD Genetics (IMAGE) Project identify two regions of suggestive linkage (16q23 and 9q22) that overlapped with prior studies. Converging regions also continue to be identified by linkage studies of dense families, e.g. 5q13 (57) and 16q23 (58), as well as of adults with the disorder, e.g. 16q23 (59). A recent genome-wide linkage study in adults also revealed significant novel loci of interest (18q21 and 2p25; (60)).

Although the linkage literature provides no replicated genome-wide significant findings using strict

criteria (61), regions highlighted by multiple studies (e.g. 5p13, 17p11, 16q23) are of considerable interest for further investigation given that these studies individually had low power to detect linkage to genes of small effects. To further delineate regions of interest among studies in this literature, Zhou et al. (62) conducted a genome scan meta-analysis of these data. They reported genome-wide significant linkage ( $P_{SR} = 0.00034$ ,  $P_{OR} = 0.04$ ) for at 16q23.1 that appeared to result from a contribution, though in some cases modest, from the majority of the seven studies examined. Additionally, results of individual and combined analyses suggest that many genes of moderately large effect are unlikely to exist in ADHD and that association methods will be more fruitful in the search for ADHD susceptibility genes.

### 109.2.3 Genome-Wide Association

Individual genome-wide association studies from the Children's Hospital of Philadelphia, an academic-industry collaboration between UCLA, Massachusetts General Hospital, University of Washington and Pfizer Pharmaceuticals (PUWMA), and two studies from the IMAGE consortium have not achieved genome-wide significant results ( $p < 5 \times 10^{-8}$ ). A meta-analysis combining these studies (63) has resulted in some promising findings, though again no results surpassed genome-wide criteria for significance. The top hit from the study (rs146807;  $p = 1.10E-06$ ) resides in a gene-poor region on chromosome 7. The next result most likely to be valid was found on chromosome 8 in a gene-rich area. The strongest signal was for rs7463256, a marker proximal to charged multivesicular protein 7 (CHMP7), involved in endosomal sorting. That study also implicated TNFRSF10D and TNFRSF10D, which are involved in mechanisms relevant to apoptosis, and LOXL2, which aids in the generation of chondrocyte, or connective tissue. As the authors note, this meta-analysis is the largest ADHD sample analyzed to date and these regions should be the bases of further study; yet, given sample sizes needed to achieve genome-wide significance for other complex psychiatric disorders, including schizophrenia and bipolar disorder, the sample lacks power to detect variants of the full range of expected effect sizes. Current efforts are now underway to amass even larger samples and are thus likely to drive power into the range where replicable genome-wide significant associations can be detected.

Exploratory analyses within GWAS data sets are also noteworthy because they highlight biological processes with a potential role in ADHD. Among the most interesting are those relevant to cellular adhesion and synaptic plasticity. For example, cadherin 13 (CDH13), which resides in the 16p23 region highlighted in linkage studies discussed above, was implicated in a pooled GWAS analyses of 343 ADHD adults and 250 controls (59) and

trait-specific analyses in the IMAGE project (64,65). Additionally, a bioinformatics pathway analysis of the five GWAS data sets has implicated proteins relevant to directed neurite outgrowth (66).

#### 109.2.4 Copy Number Variation

Finally, one of the most exciting findings to emerge in the recent literature is the presence of large (>500 kb) rare structural deletions or duplications of DNA that substantially increase risk for the psychiatric and neurodevelopmental disorders (e.g. autism (67) and schizophrenia (68)) in which they are found.

In the first investigation of this kind in ADHD, Elia et al. (69) extracted a gene set associated with copy number variants (CNVs) in their ADHD patients and parents. Compared to a large, control sample, they found no excess duplications or deletions; however, CNV-related genes were enriched for those previously identified for psychiatric disorders, learning and behavior domains and relevant neurodevelopmental processes such as synaptic transmission and central nervous system development. CNVs in the genes for protein tyrosine phosphatase (*PTPRD*) and metabotropic glutamate receptor 5 (*GRM5*) were highlighted as particularly notable because of the pattern of findings in the sample and the respectively uniform phenotypic features of patients.

Williams et al. (70) did identify an excess of rare deletions and duplications >500 kb in length in their ADHD sample (14%) versus controls (7%). Although ADHD youth with intellectual disability (ID) had a particularly high rate of these rare variants, an excess of large CNVs was still found in ADHD youth without ID compared to controls. Within this restricted group, CNVs in ADHD youth were more likely than those in controls to overlap with autism-related loci from the literature, and an excess of a particular schizophrenia-related duplication (16p13.11) was found as well. This 16p13.11 variant was also found to be a greater degree in ADHD Icelandic patients versus controls, and the replication sample showed further evidence of CNV occurrence at schizophrenia-related but not autism-related loci. There are multiple genes within this 16p13.11 region, with nuclear distribution gene E homolog 1 (*NDE1*) being of particular prior interest for schizophrenia because of its role in neurodevelopment and binding with the disrupted in schizophrenia 1 (*DISC1*) gene.

#### 109.2.5 Refined Phenotypes

Given the complexity of the ADHD phenotype, future studies will benefit from the use of large samples as well as efforts to target more homogenous and/or familial forms of the phenotype. The substantial evidence from twin studies suggesting partial rather than complete overlap for inattention and hyperactivity/impulsivity

symptoms suggests that in large samples, it will be fruitful to examine these symptom dimensions separately as well as in a combined manner. Previously, we have shown that the risk ratios in relatives of ADHD probands are increased when probands exhibit comorbidity with CD or BPD and when probands are shown to have ADHD that persists into adolescence (see Faraone et al. (71) for details). The statistical power of linkage and association studies increases with the magnitude of risk ratios. Additionally, phenotypes associated with the underlying pathophysiology of ADHD that lie in the pathway from genes to behavior are of interest to ADHD researchers. Such “endophenotypes” provide a way of targeting a phenotype that may be closer to gene products and less complex than the disorder as a whole. Thus far, endophenotypes based on neuropsychological impairments (72–74) and structural neuroimaging findings (75) appear promising in that they are identified in unaffected relatives of ADHD youth; however, considerably more work is needed to clarify their utility.

### 109.3 CONCLUSIONS

The evidence that genes influence susceptibility to ADHD continues to grow, and the field of ADHD genetics is poised for considerable advances in the coming years. In light of the changing ADHD nosology, the consistency of findings across behavioral genetic studies is striking. A growing number of candidate gene and agnostic genome-wide explorations have now been conducted. As with other neuropsychiatric disorders, the majority of genetic variance in the disorder remains unexplained. Yet promising leads exist. Meta-analyses of biological candidate genes have produced substantial evidence implicating *DRD4*, *DRD5*, *SLC6A3*, *DBH*, *SLC6A4*, *HTR1B* and *SNAP-25*; however, pooled odds ratios for these associations range from 1.16 to 1.45. Genome-wide linkage scans are not conclusive but highlight 5p13, 17p11, and 16q23 as regions likely to harbor additional susceptibility genes. Such studies also help to rule out genes of large effect in the etiology of the disorder. Although the first wave of GWAS studies has similar unyielded genome-wide significant results, they have identified the SNPs that require further exploration, and larger, better-powered studies are in the planning stages. Genome-wide data have additionally highlighted novel genes of interest, most notably *CDH13*. CNV studies have demonstrated an excess of rare duplications and deletions have been found in ADHD, and these variations overlap with other neuropsychiatric disorders, including autism and schizophrenia. In particular, a replicated duplication of 16p13.11 requires aggressive pursuit. Meta-analyses, collaborative studies with large sample sizes and examination of refined phenotypes that may reduce heterogeneity are certain to play a role in advances in the coming years. Studies of gene–gene interactions, and gene–environment interactions, will

be necessary to further clarify the mechanisms by which these genes interact with each other and with nongenetic factors. Such strategies, along with innovations in the technology and statistical methods, and opportunities for sequencing to further understand the role of rare variants, leave no doubt that further progress in understanding genetic risk for ADHD specifically, as well as risk that overlaps with other neuropsychiatric disorders, is on the horizon.

### Biographies

**Stephen Faraone** is a Professor of Psychiatry and of Neuroscience and Physiology at SUNY Upstate Medical University. He is also a Senior Scientific Advisor to the Research Program Pediatric Psychopharmacology at Massachusetts General Hospital. An author on over 700 publications, he was the eighth highest producer of High Impact Papers in Psychiatry from 1990 to 1999 according to the Institute for Scientific Information. In 2005, ISI determined him to be the second highest cited author in the area of Attention Deficit Hyperactivity Disorder and in 2007, he was the third most highly cited researcher in psychiatry for the preceding decade.

Dr Faraone is an Editor for the *Neuropsychiatric Genetics* and is a Deputy Editor for the *Journal of the American Academy of Child and Adolescent Psychiatry*, *Biostatistical and Methodology*, Editor for the *Journal of Attention Disorders*. In 2002, he was inducted into the CHADD Hall of Fame in recognition of his research on attention disorders. In 2008, he received the SUNY Upstate President's Award for Excellence and Leadership in Research. In 2009, he was awarded Alumni Fellow status at the University of Iowa. In 2010, he received the Chancellor's Award for Excellence in Scholarship and Creative Activities from the State University of New York.

**Dr Alysa Doyle** is an Assistant Professor of Psychiatry at Harvard Medical School (HMS) and on faculty of the Department of Psychiatry and the Center for Human Genetics Research at Massachusetts General Hospital (MGH). Within Psychiatry, she is a Scientific Director of Neuropsychology in the Pediatric Psychopharmacology Unit. She is also a consulting editor for the APA journal *Neuropsychology* and a licensed child and adult clinical psychologist.

Dr Doyle earned her BA in English and Psychology from Williams College. She received training in child and adult clinical psychology, pediatric neuropsychology and behavioral genetics at the University of Minnesota, where she earned her PhD. She completed her predoctoral internship and postdoctoral fellowship at MGH/HMS.

Dr Doyle's research focuses on the relationship between genes, neurocognition and risk for psychiatric disorders including ADHD, bipolar disorder, schizophrenia and autism. She also studies evidence-based clinical neuropsychological assessment in child psychiatric populations. Her work has been funded by the National Institute of Mental Health, Harvard Medical School and the Stanley Center for Psychiatric Research. She has received several awards including election to Sigma Xi by Williams College, a Dissertation Research Award from the American Psychological Association and a fiftieth Anniversary Scholars Award from Harvard Medical School.

### 110.1 BACKGROUND

Autism Spectrum Disorders (ASDs) encompass a range of illnesses that share deficits in three core domains: social interaction, restricted interests/repetitive behaviors, and language (1). In the current clinical conception, there are three major categories of ASD, autistic disorder, Asperger syndrome and pervasive developmental disorder, not otherwise specified (PDD NOS). Autism or autistic disorder describes individuals with deficits in all three domains. Asperger's disorder describes individuals with deficits in social interaction and restricted interests/repetitive behaviors, but with normal language, but is likely to be removed from Diagnostic and Statistical Manual of Mental Disorders (DSM-V), which has lumped this category into the broad concept of ASD (2,3). PDD NOS describes individuals with one or more of these core deficits who do not meet the full diagnostic criteria for autism or Asperger's disorder as defined by the DSM-IV. Also, contained within the umbrella of autism spectrum disorders in DSM-IVR are childhood disintegrative disorder and Rett's syndrome, both of which are characterized by a period of normal development followed by a loss of motor, social, or language skills. Although there is a minimum set of symptoms that a patient must have to be diagnosed with an ASD the severity of various deficits must only be enough to cause "functional impairment" to be considered as symptoms. In reality, the severity of symptoms of ASD patients lies on a broad continuum. Thus, there is a great deal of clinical heterogeneity within any group of patients with an ASD. The diagnosis of autism, much like the diagnosis of epilepsy, gives a clinician only the broadest sense of what difficulties a given patient is dealing with and says very little about the severity, etiology, or prognosis of the problem.

Thus, in addition to significant genetic heterogeneity, as we will discuss later in this chapter, the genetic study of ASDs is challenged by what many consider extreme clinical heterogeneity. Before discussing the genetics of ASDs in detail, we first provide a brief overview of ASD diagnosis, followed by a discussion of medical comorbidities. Subsequently, we explore the evidence supporting a genetic etiology for ASDs, highlight the main findings from studies of linkage, association and chromosomal structural variation, and how these exciting findings inform our understanding of ASD pathophysiology, and its relationship to other neuropsychiatric and neurodevelopmental conditions.

### 110.2 DIAGNOSIS AND CLINICAL WORK UP

Technically, any physician taking a detailed history who asks about each of the criteria set forth in the DSM-IV can make a diagnosis of an ASD. Due to the variability of people interpreting those criteria, in the last 20 years, two psychological instruments were developed that are now the gold standard in evaluations for ASDs. The first, the ADI-R, is a clinician-administered questionnaire that asks parents or caregivers about a child's development (4). The second, the ADOS, is a semi-structured battery of social interactions between a clinician and the child being evaluated that is scored in a standardized manner (5). Although the ADOS and ADI-R have been validated as being sensitive and specific in children as young as 2 years, the average age of diagnosis for children with ASDs in the United States is about 5 years (6), suggesting that systemic barriers to timely diagnosis still exist.

Current estimates about the prevalence of ASDs vary from 0.6–0.9%, but there is growing consensus that at least part of the increase in prevalence during the last four decades is due to a standardization of criteria and increased referral to specialized evaluators on the part of families, schools, and primary care physicians (7,8). Once a diagnosis of an ASD is made, further evaluations such as a neurological evaluation, speech/language testing, audiology testing, IQ testing, and physical/occupational therapy evaluations are warranted to identify targets for treatment (9). In order to help distinguish between syndromic and idiopathic forms of ASDs, a detailed physical examination looking for dysmorphic features as well as Woods' lamp examination of the skin are recommended by the American Academy of Pediatrics (10). The development of array based comparative genomic hybridization and cytogenetic microarray technology has made genetic evaluation valuable in ASDs as well. Recent studies have determined that between 10 and 20% of patients with ASDs will have duplications or deletions that are identified by these tests, results observed in the American College of Medical Genetics recommend them as first-tier tests for patients with ASDs (11).

### 110.3 MEDICAL COMORBIDITIES

In addition to behavioral symptoms, individuals with ASDs can have variable impairments in sensory, motor, and medical domains (see Reference (12) for review). Classically, it was thought that 60–70% of individuals with autistic disorder have intellectual disability (ID) (13,14), but more recent estimates range between 34 and 55% (15–17). Epilepsy is highly comorbid with ASDs, though estimates of epilepsy prevalence in the ASD population vary from 6 to 60%. The higher estimates are due to inclusion of syndromic forms of ASD with a high occurrence of seizures, such as Tuberous Sclerosis Complex (TSC), and the prevalence of epilepsy in idiopathic ASD likely ranges between 5 and 10%. The loss of developmental milestones or skills after a period of normal development (developmental regression) is sometimes seen in patients with ASDs as well as certain syndromic forms of epilepsy (e.g. Dravet syndrome) (18). Although the definition of regression was not constant across studies, recent work has estimated the prevalence of developmental regression in ASDs to be between 22–53%, with the median age at the start of regression being between 20 and 30 months (19–21). Patients with developmental regression and autism may represent a subtype of ASDs with their own etiology, however they do not appear to have differences in prognosis or eventual levels of functioning compared to ASD patients without developmental regression (22).

Several studies have demonstrated that the mean head circumference in individuals with autism is larger than average; the rate of macrocephaly in ASD is between 17 and 20% (compared to 3% in the general population) (23,24). Courchesne et al. have presented evidence that

this may be due to brain overgrowth during the first year of life (25,26). Taken together, these findings indicate that the ASDs are caused by problems in early neural development and emphasize the importance of understanding developmental trajectories in addition to single epochs over time.

### 110.4 ETIOLOGY: GENES AND THE ENVIRONMENT

The purpose of this chapter is to review the literature concerning the genetic basis for ASDs, however there is an ongoing debate about what fraction of an individual's risk for having an ASD is due to genetic factors and what fraction is environmental. Rather than predicting the outcome of this debate, we take the position that the genetic data from genome sequencing and other efforts will help to settle this issue.

The first evidence implicating genetic factors was the discovery of chromosomal rearrangements in cases of autism, as well as the recognition that patients with certain rare genetic syndromes had deficits in the three core domains of ASDs. Some of the most important evidence supporting a major role for genes in ASDs come from twin studies (reviewed in Reference (27)). Early twin studies, using a more stringent definition of autism, found a high concordance among monozygotic (MZ) twins and almost no concordance among dizygotic (DZ) twins; these relatively small studies estimated that genetic factors comprised about 90% of the risk (28–30). More recently, larger twin studies have shown lower rates of concordance compared to the earlier studies among MZ twins (39–58%), and modestly increased rates of concordance among DZ twins (24–31%) (31,32). This suggests that the contribution of genetic factors to risk for ASDs is still significant and consistent with a heritability of 0.7. Although this heritability estimate is relatively large, it is on the lower end of previous estimates.

Previous studies have estimated that the sibling recurrence risk for ASDs (the odds that a future sibling of a child with an ASD will also have an ASD) to be between 3 and 10% (16,33,34). The most recent large scale, multisite prospective study of recurrence risk found it to be about 20% for autism (35), similar to the risk observed in DZ twins. This figure does not leave much room for sharing in utero environmental factors in ASD etiology. Other evidence for genetic factors playing a role in ASDs includes the heritability of subthreshold “autistic traits,” such as increased head circumference, and social dysfunction, as well as psychometric properties of language (14,24,32), which will be discussed later in the section on endophenotypes.

There is also evidence that environment can play a role in the occurrence of ASDs. In the 1960s an association was found between maternal viral infection during pregnancy (particularly rubella) and autism (36,37). Prenatal exposure to the antiepileptic drug sodium

valproate also significantly increased the risk of developing an ASD (38). If we assume the general population prevalence for ASDs to be about 0.8%, we can calculate the rough odds ratios (OR) for prenatal rubella infection or valproate exposure leading to ASDs as at least 9.9 and 6.0, respectively, which is higher than common genetic risk factors. Another environmental risk factor is increased parental age. Several studies have now replicated the finding that increased maternal and paternal age are associated with increased odds for ASDs in offspring, ranging from 1.3–1.6 for a single older parent to 3.1 if both parents are >40 years old at conception (39–41). A recent study by Volk et al. showed that the distance of maternal address during pregnancy from freeways was inversely correlated with risk for ASDs (42). The study showed the greatest OR of 2.2 for developing ASDs when mothers lived near a freeway during the third trimester. This suggests that airborne pollutants may play a role as well. Given the fact that all the subjects in the study were from a single geographic area (California), the study needs to be replicated in other parts of the world. Additionally, no actual airborne pollutants were measured in the study; proximity was taken as a surrogate measure of exposure. Many confounders are possibly explanatory and further work in this area is clearly needed.

Given the clear evidence for both genetic and environmental factors in ASD etiology it is not really that productive to argue which is more important. Common conditions are caused by a combination of genes and the environment, not one or the other. The benefit of a genetic approach is that it is a practical and efficient means to identify the etiologies of ASDs. One important issue that is often not discussed is that heritability estimates cannot take into account relatively invariant or pervasive environmental factors, which may be acting in concert with genetic factors. However, once genetic risks are identified, they provide a window through which environmental factors can be explored in an efficient manner.

### 110.5 PATHOPHYSIOLOGY

As ASDs are pediatric brain disorders and those with ASD do not have a shortened lifespan, obtaining post-mortem tissue for histopathological analysis has been challenging. Consequently, most pathological studies have had very small sample sizes and it has been difficult to compare across conditions and methodologies. Despite these limitations, two groups have made the observation that there appears to be an increase in the number of cortical mini columns in the brains of individuals with autism (43–45). These mini columns appear smaller in size, but contain a normal number of neurons, consistent with higher neuronal packing density overall. There has also been one report of an increase in cortical dendritic spine density in specific brain regions of

**TABLE 110-1** Syndromes with ASD as a Component

12p13 (Timothy)	60–80	(99–102)

<sup>a</sup>There exist some controversy whether or not the stereotypies and social deficits seen in Angelman syndrome are more related to ID than ASDs (see Reference (103) for review).

individuals with autism (46). These data, combined with fMRI and EEG studies (47–50), have led to the hypothesis that there is an overabundance of local neuronal connections within certain brain regions, at the expense of long-range (interhemispheric) connections (reviewed in Reference (51)). Another hypothesis about the pathophysiology of autism states that there is an imbalance between excitatory and inhibitory inputs (E–I imbalance) to neurons in various brain regions (52,53). Evidence for this theory comes from the observation of the comorbidity of epilepsy with ASDs (Table 110-1) as well as direct measurements in animal models of syndromic forms of autism (reviewed in Reference (54)). A third hypothesis, called the extreme male brain theory, posits that individuals with ASDs have brains in which exaggerated sex differences in neuro-circuitry result in differences in how they respond to social and other stimuli (55). Proponents of this theory argue that it helps explain the 4:1 male to female ratio seen in ASD cases and point to studies in which the levels of testosterone that a fetus was exposed to were later correlated with behaviors associated with ASDs (56,57). None of these theories is mutually exclusive and given the clinical heterogeneity of individuals with ASDs, all of them may help explain a proportion of cases. Our view is that the genetic data provides a solid and unbiased platform for understanding ASD

pathophysiology. Below, we first review chromosomal structural variation, followed by linkage and association.

## 110.6 SYNDROMIC FORMS OF ASD AND STRUCTURAL CHROMOSOMAL VARIATION

It has been estimated that 6–7% of individuals with ASD have large structural chromosomal variations visible with standard cytogenetic methods (58). Although analysis of common genetic variation based on SNP microarrays has not yielded strong genome wide association signals (see later in this chapter), these same data have been successfully used to identify structural chromosomal variation (59–61). Since the first studies showed that de novo nonrecurrent copy number variation (CNV) caused about 5–10% of ASDs (58,62), array technology has been steadily improving the resolution of rearrangements that can be identified (reviewed in Reference (63)). This led to the identification of several of the recurrent events discussed in Table 110-1, such as 16p del/dup. Two recent CNV studies in ASDs have identified the candidate genes *BZRAP1*, *MGDA2*(64), *SHANK2*, *SYNGAP1*, *DLGAP2*, and *PTCHD1*(60). These studies used either multiplex (more than one affected family member) or a combination of simplex (only one affected child) and multiplex families. Two more recent CNV studies have been on a collection of exclusively simplex families collected to help identify de novo events that contribute to ASDs (65). Sanders et al. found significant association between CNVs at 7q11.23(duplication), 16p13.2, and 15q11–13.1 in the Simons simplex collection (61). A parallel study by Levy et al. used a different platform and statistical tools on the same sample, and found consistent results, including an increased frequency of CNVs in girls; neither study identified an excess of transmitted CNVs in ASD, consistent with the model that the major risk conferred by CNV in ASDs is due to de novo events (59). Interestingly, an accompanying pathway analysis of the genes identified in the Levy et al. paper confirmed many of the candidate genes identified by a previous study (60) and implicated pathways involved in synapse formation and dendritic morphogenesis (66). But, despite a more than 10-fold increase in resolution over the last 5 years, the proportion of ASD that can be explained by large (>250kb) de novo CNV remains between 5 and 10%. It is also important to emphasize that although none of these variations individually account for more than 1% of total cases of ASDs, several of these CNVs and other syndromic forms of ASDs show a very high penetrance for ASD (see Table 110-1). These mutations with large effect sizes, including CNV spanning many genes, as well as syndromic forms of ID, have provided the first clear candidate genes for ASDs.

The identification of these syndromic forms of ASD is important because certain syndromes have other features relevant to treatment associated with them. For example,

sudden cardiac death is observed with increased frequency in 15q11–13, while astrocytomas and renal cell tumors are associated with TSC. As many of the newer syndromes become better clinically characterized, differences in phenotypes and trajectories are likely to be identified. A salient example is the difference in head circumference in 16p deletion versus 16p duplication patients (78,104), and the much lower penetrance for ASD and broader phenotypes observed in those with 16p duplication versus those carrying the deletion (76–78,105). Because of these issues, a molecular diagnosis is likely to be quite important from a clinical standpoint, especially as our characterization of some of the more recently identified CNV associated with ASD are studied in larger populations.

## 110.7 LINKAGE AND ENDOPHENOTYPES

### 110.7.1 Linkage Studies

Over the past decade, large linkage studies have identified numerous regions of interest that have met genome wide significance (3q25–27(106), 2q, 7q(107), 17q11–q21(108), and 20p13(109)), but only two (7q(110) and 17q11–q21(111)) have been replicated. Within these replicated linkage regions and others, where it has been assessed, no single common variant can account for the linkage signals (112,113). The lack of replication of large linkage studies is thought to be due to the heterogeneity present in ASDs. The lack of common variant association that can explain linkage under replicated peaks suggests that rare genetic variants play a more important role than previously realized.

### 110.7.2 Endophenotypes

One way to tackle heterogeneity is to use clinical features to identify what one hopes to be a more homogeneous subset of patients. For example, those with epilepsy, large heads, specific psychiatric comorbidities, ID, language delay, or even sex, may have distinct genetic risk factors. Multiple groups have devised strategies that perform linkage analyses for ASDs after stratification by phenotype with varying success. Stone et al. found a male specific linkage peak at 17q11 that reached genome wide significance (114). Molloy et al. (also using the Autism Genetic Resource Exchange (AGRE) sample) found suggestive peaks at 7q and 21q in ASD cases with regression (115). Salyakina et al. stratified for language by only analyzing cases with Asperger's disorder and found suggestive linkage peaks at 5q21 and 15q22 (116). When stratifying by IQ in the AGP dataset, Vieland et al. did not find any genome wide significant peaks, but did find that high and low IQ cases had distinct, mutually exclusive patterns of linkage (117). As with any such genetic finding, replication is critical, and the only finding from

stratification that has been formally replicated is the male-related locus on chromosome 17 (111).

Another approach uses the power of continuous quantitative traits of ASD features to find chromosomal regions of interest (reviewed in Reference (118)). Such quantitative endophenotypes should be observed in those with the disease and heritability (observed in those with the disorder and first degree relatives more than in the general population) (119). In theory, this QTL approach is more powerful than stratification, as it allows one to use all subjects, affected and unaffected, and does not require creating smaller subgroups of patients with a particular feature, which can reduce power by reducing sample size.

Several groups have adopted the idea that the overlapping genetic risk across ASDs, other psychiatric disorders, and the general population (120–123) represent a continuum of neurodevelopmental vulnerabilities and function. The existence of a “broad autism phenotype,” or subclinical features of ASDs found in family members of patients also argues that ASDs are an amalgam of traits (124) and the clinical heterogeneity of ASDs comes from the particular mix of traits observed in a given individual. Considerable progress has been made in defining those traits, determining their heritability, and developing psychometric instruments to quantitatively measure them in the past decade (reviewed in Reference (125)). Sung et al. found that traits for social motivation and range of interest/cognitive flexibility had the highest heritability (126). Wheelwright et al. developed an Autism Spectrum Quotient questionnaire that may be useful stratifying the patients with ASDs, but needs to be validated (127). Recent genome-wide scans have used older measures such as IQ (128), ADI-R subscales (129), and language delay (130) to identify loci of interest, but none have reached genome-wide significance.

As new measures and traits are identified, a comprehensive approach to identify the best endophenotypes for genetic study of ASD is needed. Genome-wide scans based on these traits are more likely to be successful than previous studies, which relied on targets of convenience, such as age of first word on ADI or IQ testing. Large-scale studies of the segregation of specific cognitive and behavioral features are needed in ASDs and across allied psychiatric diseases (see later in this chapter on cross disorder mutations).

## 110.8 GENOME WIDE ASSOCIATION STUDIES

Several genome wide association studies (GWAS) in ASD have been performed, but they have not revealed any loci with major effect sizes. Wang et al. published a high density SNP GWAS involving 2503 affected individuals and 6491 control subjects, starting with 1299 individuals from multiplex AGRE families. They found six SNPs in an intergenic region between the cell adhesion genes *CDH9* and *CDH10* as having replicated, genome wide

significance (131). Weiss et al. studied 1553 affected individuals, including a set of approximately 1175 individuals from AGRE that largely overlaps with the Wang et al. study. Weiss et al. found one highly suggestive SNP between the axon guidance factor *SEMA5A* and the taste receptor gene *TAS2R1* (109). These two studies, using different platforms, but a largely overlapping group of AGRE families, did not replicate each other’s findings. One possible explanation for this fact is that the two platforms had different areas of coverage (i.e. the platform used in Weiss et al. had poor coverage in the region identified by Wang et al. and vice versa). In light of a third study that failed to replicate either group’s findings (132), one has to consider the alternative that these initial findings are not generalizable. This is in contrast to the CNV studies mentioned earlier that have largely been consistent in their findings.

## 110.9 CANDIDATE GENES

To date, the list of genes that have been preliminarily associated with ASD (affected by CNVs or mutations) has over 100 members, representing a wide range in the level of supporting evidence (see Reference (63) for review). As multiple groups embark on whole genome and exome sequencing projects on patients with ASDs, this list is likely to change. Making sense of this growing list of genes presents a conceptual and bioinformatic challenge. One popular approach is to use gene ontology databases to order the genes on the list into common biological processes, and then construct networks between the genes based on different models of interaction (60, 132). There are several caveats to recognize with this approach. The first is that the candidate genes for ASDs are so disparate, that most biological processes undertaken by neurons are implicated. The second problem, which is related to the first, is that the approach is dependent on the quality and specificity of the gene ontology assignments, which vary greatly among genes. A more useful approach might be to categorize candidate genes based on their presence in biochemical complexes or pathways. The downside of this approach is that a greater number of the genes would remain uncategorized due to a lack of understanding of their biology. Table 110-2 outlines some of the biochemical pathways containing multiple ASD candidate genes.

In addition to the pathways mentioned in Table 110-2, there are several categories of proteins that contain members linked to ASDs that are intriguing as possibilities for future research. These include Actin regulators (*SYNGAP1*, *CYFIP1*, *ARHGEF6*, *NHS*), microtubule regulators (*LIS1*, *YWHAE*, *DCX*), ion channels and their regulators (*SCN1A*, *PRSS12*, *CACNA1c*, *CACNA1f*, *SLC9A6*, and *GRIA3*), transcription factors (*MEF2C*, *HOXA1*, *SATB2*, *FOXP1*, *FOXP1*, *FOXP1*, *RAI1*, *ARX*, *NFIX*, *TBX1*, *ZNF81*, *ZNF674*), and proteins involved in vesicle transport (*OCRL*, *AHI1*, *VPS13B*, *SYN1*, *RAB39B*).

<sup>a</sup>For references showing that these genes are linked to ASDs, see Reference (63). Genes within parentheses are known to form complexes.

A major unanswered question is whether these pathways converge on common molecular or biological processes (156,157). Recent gene expression studies in ASD brain suggest that despite the disparate processes implicated by mutations, there may be a large degree of convergence on final common pathways (158). This exciting finding awaits broader replication.

### 110.10 VARIABLE EXPRESSIVITY AND VARIABLE PENETRANCE—PSYCHIATRIC COMORBIDITY AND DISEASE BOUNDARY CONFUSION

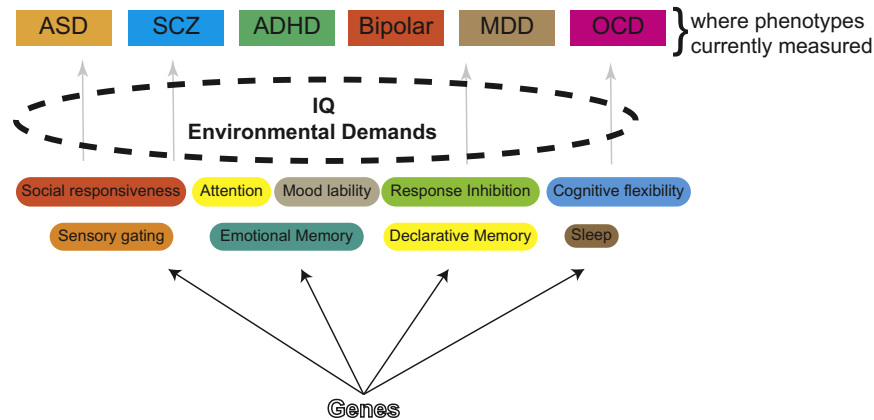

As our genetic knowledge advances, the classic boundaries that separate psychiatric diseases are being called into question; multiple genes and chromosomal regions implicated in ASDs have also been implicated in other psychiatric disorders such as schizophrenia, ADHD, and OCD (159). This raises the questions of variable penetrance and expressivity, or why mutations in a given gene can produce such different outcomes in different people? Another fundamental problem in the genetics of neuropsychiatric disorders is that the phenotypes used to assess penetrance, linkage, or association, are clinical assessments based on functional impairment that are far from the actual genetic derangement.

Figure 110-1 illustrates the concept that genes are likely to impact basic behavioral capabilities or parameters rather than specific disorders. Deficiencies in these capabilities can then interact with an individual's environment to form the constellations of symptoms we recognize as neuropsychiatric disorders. As a corollary, certain environments such as those found in wars, natural disasters, or extreme poverty, can overwhelm most people's functional reserve and produce symptoms in the absence of obvious genetic risk; however, the clinical manifestation of a mutation may not be observed until the individual's capacity to compensate is exceeded. From this perspective, resiliency or functional reserve may mask the effects of specific causes. Therefore, in order to understand the roles of specific genes in neuropsychiatric disorders, it may be more productive to ignore issues of penetrance and instead focus on understanding variable expressivity.

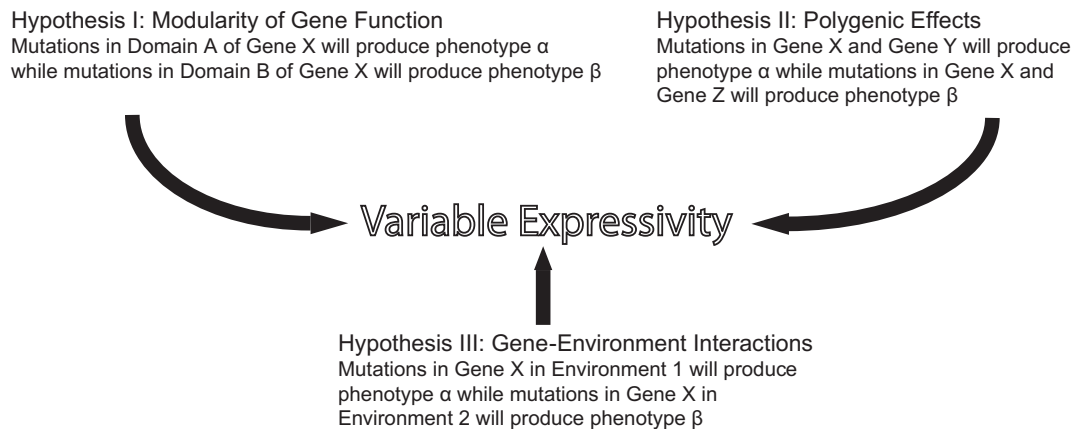

Understanding the mechanisms of variable expressivity in ASD candidate genes is important because they may help explain why there is such a great deal of clinical heterogeneity in ASDs. Additionally, being cognizant of these mechanisms is important because they form implicit assumptions that influence the design and analysis of genetic experiments. In many cases, studies are designed to minimize sources of variable expressivity. For example, researchers who believed that random X inactivation was a major source of variable expressivity may choose to study a disorder only in males or choose to focus on candidate genes on the X chromosome. Researchers who believed that an environmental factor, such as exposure to power lines, caused variable expressivity would choose to study their disorder in more rural populations.

Figure 110-2 illustrates three broad hypotheses about mechanisms of variable expressivity in ASDs. None of the hypotheses are mutually exclusive and, as we will now discuss, all have some evidence that they are relevant to ASDs.

The most obvious examples of Hypothesis I would be instances of pleiotropy, or one gene having multiple functions. However, mutations in regulatory regions, splice sites or imprinted genes would also be examples where the location of the mutation determines what disorder it produces. Recent re-sequencing efforts and deleterious SNPs found in a few ASD candidate genes offer the opportunity to see if Hypothesis I can be supported. *NRXN1* is a gene with considerable evidence linking it to ASDs, schizophrenia, and ID (reviewed in Reference (160)). Gauthier et al. re-sequenced the coding exons of *NRXN1* in individuals with ASDs, schizophrenia, non-syndromic Intellectual Disability (NSID), and controls, identifying rare variants that were more strongly associated with ASDs or schizophrenia (161). Looking at their data, one finds the interesting pattern that none of the missense mutations in *NRXN1* associated with just ASDs, or just schizophrenia and not with NSID, or controls, fall within a known domain (according to the NCBI Conserved Domain Database). In contrast, all of the missense mutations associated with NSID fall within one of the Laminin G domains of the protein. Re-sequencing of a related ASD candidate gene, *CNTNAP2* revealed rare

**FIGURE 110-1** Phenotypes in neuropsychiatric disease. Many neuropsychiatric genetic studies look for association or genetic effect at the level of neuropsychiatric disorders. However, these disease categories are predicated on functional impairment caused by a combination of environmental demands exceeding individual capabilities and compensatory mechanisms (which can often be influenced by IQ). ASDs provide an example of this where early-identified cases all had cognitive impairments and only after a seismic shift in awareness on the part of parents, educators, and clinicians were higher functioning cases identified. Individual genes are far more likely to impact basic behavioral traits such as the ones described. (Abbreviations: ASD: Autism Spectrum Disorder, SCZ: Schizophrenia, ADHD: Attention Deficit Hyperactivity Disorder, Bipolar: Bipolar Disorder, MDD: Major Depressive Disorder, OCD: Obsessive Compulsive Disorder.)

**FIGURE 110-2** Mechanisms of variables expressivity. Three plausible mechanisms for how variable expressivity can be observed when mutations in a hypothetical gene “X” are present. In this scenario, phenotype  $\alpha$  could be the disease state most often associated with Gene X, while phenotype  $\beta$  could be either another illness, or no illness (healthy individual). It is important to note that none of these hypotheses are mutually exclusive and they each may be true for a given gene in different biological contexts.

variants associated with ASD scattered throughout the protein (162), while studies looking at common variants associated with specific language impairment or selective mutism in the general population found significant SNPs clustering between exons 13–15 of the gene (163,164). As more sequencing efforts are published, we are likely to find more examples of different mutations in a given gene producing different neurobehavioral phenotypes, motivating cross disorder study of genetic risk factors that rely on careful quantitative measurement of behavior, cognition, and brain anatomy and function, rather than categorical disease diagnoses.

It is clear from genetic studies that ASDs are unlikely to be single gene disorders. Hypothesis II, which states that different combinations of mutations result in different phenotypes, provides a plausible explanation for how a polygenic, or complex genetic disease could have

significant clinical heterogeneity. The first evidence that Hypothesis II was applicable to ASDs was the observation that large deletions of candidate genes (presumably null mutations) were not fully penetrant in families (see Table 110-1, (165)). Early exome sequencing efforts of patients with ASDs have also identified rare variants that appear be associated with ASD when found together, but not in isolation (166). Gregor et al. re-sequenced two candidate genes (*NRXN1* and *CNTNAP2*) whose homozygous deletion is strongly associated with ASDs and ID in a population with ID and found heterozygous deleterious mutations in the two genes in a significant number of cases (167). This suggests that other genes are likely interacting with these two to produce ID. Levy et al. provided evidence for the idea that that ASDs are rarely caused by single gene mutations, but more often by CNVs that affected multiple genes, particularly in girls

(59). Again, further exome and whole genome sequencing will give us a clearer picture about how much of the clinical heterogeneity of ASDs is explained by Hypothesis II.

The previous two hypotheses assume that ASDs are result of aberrant neuro-developmental programs caused by one or multiple mutations. There is an alternate view that considers ASDs to be the result of an event, possibly a developmental insult. As reviewed earlier, several lines of evidence point to something happening either prenatally or during the first 6 months of life that results in a child displaying features of an ASD. Hypothesis III argues that the clinical heterogeneity of ASDs is due to a combination of the timing or nature of the insult and the patient's genetic background, which would confer varying levels of susceptibility to the insult. While we currently only have faint clues about what that insult might be (maternal infection, environmental contaminants, etc.), support for Hypothesis III exists in the findings that there appear to be haplotypes in the EN2 (168,169) and HLA DRB1 (reviewed in Reference (170)) loci that are protective for ASDs. Hypothesis III also offers a framework for considering epigenetic risk factors for ASDs. Hypothesis III is concordant with the idea that synaptic dysfunction is at the root of all psychiatric disorders in the same way that aberrant blood-flow is at the root of all strokes. In this model, the behavioral differences between schizophrenia, major depressive disorder, and ASDs result from different circuits, or populations of neurons being affected. If this were the case, one would expect to see a greater frequency of other psychiatric disorders in the families of patients with ASDs. Several small studies have suggested an increased prevalence of mood and anxiety disorders in the first degree relatives of patients with ASDs (171–173), but a large systematic investigation into the neuropsychiatric disease burden in families with ASDs needs to be undertaken.

It should be clear from the previous discussion that the genetic findings to date have not simplified our notion of psychiatric disease. From a clinical perspective, the issue of psychiatric comorbidity in ASDs is one that the field is still struggling with. Several of the diagnostic features or commonly associated symptoms of ASDs overlap with other disorders, such as sleep problems (overlapping with bipolar disorder), cognitive rigidity and repetitive behavior (overlapping with Obsessive Compulsive and Tic disorders), and social difficulties (often seen in ID or Social Anxiety Disorder). The DSM IV-TR and ICD-10 explicitly exclude diagnosing a patient with both ADHD and ASD, despite the fact that patients with ASDs frequently have symptoms of hyperactivity and difficulty paying attention (174). Parsing a patient's symptoms into subtly different categories often hinges on the patient's subjective experience of the symptoms, which can be difficult to elicit or correctly interpret in the case of patients with

ASDs due to their language and cognitive deficits. Furthermore, internal states such as sadness or anxiety may manifest through vastly different behaviors in patients with ASDs compared to neurotypical children. This has made quantifying the rates of comorbid psychiatric disorders with ASDs problematic. Our position is that researchers should essentially ignore these relatively arbitrary disease boundary issues, which are primarily useful for clinical reasons.

## 110.11 CONCLUSION

The clinical and genetic heterogeneity of ASDs have led to the suggestion that ASDs encompass hundreds of unique “autisms” (12), but this may be true of many neuropsychiatric disorders. The genetic data outlined in this chapter as well as what will be published in the near future promise to help resolve these clinical issues. As the many genes implicated in ASDs are organized and validated in pathways, biomarkers may be found for their dysfunction and specific therapeutic targets can be identified. Given the issues of variable expressivity we have highlighted (many ASD candidate genes are also implicated in other neuropsychiatric disorders), which specific quantitative cognitive, behavioral, biochemical or anatomical traits are influenced by particular genetic risk variants is a critical area of work in the near future. It is certainly plausible that such etiological information will lead to major revisions in diagnostic categories. A robust understanding of the genetics will finally give us improved diagnostic clarity, improved family and genetic counseling, as well as help guide treatment and prognostication. In the end, such information as to disease mechanism will serve to augment practice by providing individualized care, thus supplementing wise clinical practice and enabling us to truly treat the patient rather than the disorder.

### Biographies

**Daniel Geschwind** is the Gordon and Virginia MacDonald Distinguished Professor of Neurology, Psychiatry and Human Genetics, and Director of the Neurogenetics Program and Center for Autism Research and Treatment in the Semel Institute at UCLA.

Geschwind obtained an AB degree in psychology and chemistry at Dartmouth College and his MD and PhD. degrees at Yale University School of Medicine. He completed his neurology residency at UCLA in 1995, where he has remained following training, joining the faculty in 1997. Dr Geschwind's research is in the area of neurogenetics and systems biology of human neuropsychiatric diseases.

His laboratory integrates basic neurobiology, genetics and genomics with translational studies of human diseases, ranging from autism to neurodegenerative diseases. Dr Geschwind has also put considerable effort into fostering large-scale collaborative patient resources for genetic research and data sharing. He played a major role in the founding and has provided scientific oversight for the Autism Genetic Resource Exchange (AGRE). He has published over 500 on numerous scientific advisory boards, including the NIH Council of Councils, the NIMH scientific advisory council, and the Faculty of 1000 Medicine. He received the Derek Denny-Brown Neurological Scholar Award from the American Neurological Association in 2004 and the Scientific Service Award from Autism Speaks in 2007.

**Sunil Mehta** is currently a Child and Adolescent Psychiatry fellow in the Semel Institute at UCLA. He received his BA in Biology and Philosophy of Science from the University of Pennsylvania and his MD and PhD degrees from Baylor College of Medicine. He completed his adult psychiatry residency at UT Southwestern Medical Center in 2009. Dr Mehta's research interests focus on understanding the biological functions of ASD candidate genes. He is currently using the visual system of *Drosophila melanogaster* to study the function of several ASD candidate genes.

### 111.1 BACKGROUND AND HISTORY

Alzheimer disease (AD) is characterized by an insidious onset and progressive deterioration of memory and at least one other cognitive domain (language, praxis, recognition, or executive functioning). It is the leading cause of dementia in the elderly, affecting more than 5.4 million people in the United States (1,2). Prevalence increases with age, from 0.3–0.5% at age 60 to 11–15% at age 80 (3–5). There is substantial variability in these estimates, with some reports finding the prevalence to be as high as 47% after age 84 (6). Half the beds in long-term care facilities are already devoted to patients with dementia, and a majority of those patients have AD (7). As the population continues to age, the prevalence is expected to increase almost threefold by 2050 (1), making AD a growing public health and economic crisis.

#### 111.1.1 Alzheimer Disease History

In 1906, Bavarian psychiatrist Alois Alzheimer presented the first case of dementia characterized by histopathological signs of senile (neuritic) plaques and neurofibrillary tangles (NFTs). At the time, Alzheimer thought the disease was a rare cause of senility (8). In the 1960s, Blessed, Tomlinson, and Roth performed a series of autopsies on hundreds of brains affected with “normal senility” (9), and found the majority were affected by the plaque and tangle lesions characteristic of AD. In subsequent decades, it became increasingly clear that most dementias result from a specific pathological process, and are not simply the result of aging.

Despite advancements in clinical assessment, definitive diagnosis of a symptomatic person still requires either neuropathologic examination of brain tissues obtained postmortem, or pathogenic mutation in a causal AD gene (10–12). Further complicating the diagnosis for clinicians, 6–14% of autopsy confirmed cases have an atypical disease presentation (10,13–15).

Clinically, AD remains a diagnosis of exclusion, generally beginning with slowly progressive memory loss, and advancing to deficits in higher intellectual functions and cognitive abilities (16). Even an apparently clear clinical diagnosis of AD may be overturned later by histopathological investigation, revealing different or additional etiologic processes contributing to cognitive impairment (17). Standard criteria for the clinical diagnosis of AD were established by the National Institute for Neurological and Communicative Diseases and Alzheimer’s Disease and Related Disorders Association (NINCDS-ADRDA criteria) in 1984 (18) (Table 111-1). In tertiary care facilities, clinical diagnosis is accurate in 85–90% of putative AD cases (19–21). Clinical diagnosis of AD in individuals aged 60 years and older is often complicated by numerous factors including cerebrovascular insults (22) and common, co-occurring neuropsychiatric conditions (23). In a study by Carney et al. (24), 9 of 101 clinically diagnosed cases of AD from a family research study had a different etiology for their dementia, including two within the same multiplex family. Another 18 cases had unrecognized contributing comorbidities in addition to AD pathology. Most of the cases with disparate clinical and histopathological diagnoses had significant Lewy body pathology, but Pick disease and progressive supranuclear palsy also contributed.

**TABLE 111-1 Criteria for Clinical Diagnosis of Alzheimer Disease**

- I. The criteria for the clinical diagnosis of probable Alzheimer disease include
  - Dementia established by clinical examination, documented by the Mini-Mental Test, Blessed Dementia Scale, or some similar examination, and confirmed by neuropsychological tests
  - Deficits in two or more areas of cognition
  - Progressive worsening of memory and other cognitive functions
  - No disturbance of consciousness
  - Onset between ages 40 and 90, most often after age 65
  - Absence of systemic disorders or other brain diseases that in and of themselves could account for the progressive deficits in memory and cognition
- II. The diagnosis of probable Alzheimer disease is supported by
  - Progressive deterioration of specific cognitive functions, such as language (aphasia), motor skills (apraxia), and perception (agnosia)
  - Impaired activities of daily living and altered patterns of behavior
  - Family history of similar disorders, particularly if confirmed neuropathologically
 Laboratory results of
  - Normal lumbar puncture as evaluated by standard techniques
  - Normal pattern or nonspecific changes in electroencephalograph such as increased slow-wave activity
  - Evidence of cerebral atrophy on computed tomography, with progression documented by serial observations
- III. Other clinical features consistent with the diagnosis of probable Alzheimer disease, after exclusion of causes of dementia other than Alzheimer disease, include
  - Plateaus in the course of progression of the illness
  - Associated symptoms of depression, insomnia, incontinence, delusions, illusions, hallucinations, catastrophic verbal/emotional/physical outbursts, sexual disorders, and weight loss
  - Other neurologic abnormalities in some patients, especially with more advanced disease and including motor signs, such as increased muscle tone, myoclonus, or gait disorder
  - Seizures in advanced disease
  - Computed tomography normal for age
- IV. Features that make the diagnosis of probable Alzheimer disease uncertain or unlikely include
  - Sudden, apoplectic onset
  - Focal neurologic findings such as hemiparesis, sensory loss, visual-field deficits, and incoordination early in the course of the illness
  - Seizures or gait disturbances at the onset or very early in the course of the illness
- V. Clinical diagnosis of possible Alzheimer disease
  - May be made on the basis of the dementia syndrome, in the absence of other neurologic, psychiatric, or systemic disorders sufficient to cause dementia, and in the presence of variations in the onset, in the presentation, or in the clinical course
  - May be made in the presence of a second systemic or brain disorder sufficient to produce dementia, which is not considered to be the cause of the dementia
  - Should be used in research studies when a single, gradually progressive severe cognitive deficit is identified in the absence of other identifiable causes
- VI. Criteria for a diagnosis of definite Alzheimer disease are
  - The clinical criteria for probable Alzheimer disease
  - Histopathologic evidence obtained from a biopsy or autopsy
- VII. Classification of Alzheimer disease for research purposes should specify features that may differentiate subtypes of the disorder, such as
  - Familial occurrence
  - Onset before age of 65
  - Presence of trisomy 21
  - Coexistence of other relevant conditions, such as Parkinson disease

### 111.1.2 Heritability and Segregation within Families

Several lines of evidence support heritable components of AD. Familial aggregation studies demonstrate the disease clustering within families (25–27), and in large pedigrees with early-onset Alzheimer disease (EOAD), the disease exhibits an autosomal dominant pattern of inheritance (28). Family studies of AD have found that the age at onset (AAO) of AD within families has a bimodal distribution. EOAD families were determined empirically to have a mean AAO less than 58 years (29). EOAD is generally defined as an onset of symptoms prior

to age 60 or 65 (30–32). Twin studies have also demonstrated a genetic component to AD. By their nature, twin studies of the elderly tend to be small, and early studies utilized varying diagnostic criteria; however, each published study found the concordance rate among monozygotic twins (22–83%), who share all their genes, to be higher than the concordance rate among dizygotic twins (0–50%), who share only half their genes on average (33–36). While the higher concordance rate in monozygotic twins supports the genetic influence on the disease, environmental factors are also suspected, since concordance was not 100%.

Segregation analysis in families affected by AD further supports the influence of genes on AD risk. Segregation analysis follows the inheritance of a disease through a family and attempts to fit a genetic model to the observed transmission pattern. Models assuming only sporadic AD with no major genes and models limited only to Mendelian inheritance patterns were rejected (37). Using only EOAD families, the pattern of inheritance is often consistent with classic Mendelian autosomal dominant inheritance, while inheritance patterns in late-onset families appear more complex. Late-onset Alzheimer disease (LOAD) follows a pattern of multifactorial inheritance involving a combination of genetic and nongenetic factors (38–40).

In summary, these studies have provided powerful evidence for a genetic contribution to AD, even before any specific genetic variants were identified. In the very rare early-onset autosomal dominant pedigrees, the evidence clearly points to Mendelian genes. Additional risk-conferring genetic variants inherited in more complex combinations were believed to contribute to AD in the majority of the population.

### 111.1.3 Environmental Risk Factors for AD

As noted earlier, the lack of perfect concordance in AD status among identical twins, who share 100% of their genes, strongly implies that not all risk for AD is attributable to genetic effects. In fact, a variety of environmental factors have been implicated in AD risk including socioeconomic features such as level of education, a multitude of risk factors for cardiovascular disease, and still others such as history of head injury and female gender. Immune pathways have also been implicated in AD.

Environmental risk factors of AD have been reviewed in considerable detail elsewhere (41). Major socioeconomic factors implicated in increases of AD risk include lower level of income, lower level of completed education, and lower occupational status (42). These factors are correlated with poor quality of and limited availability of resources needed during childhood development that tend to be associated with poor growth and physical development (42). These limitations contribute to developmental markers like low birth weight (LBW) and short stature, which have been shown to be associated with AD (43). LBW is often a marker of developmental deficiency and often correlates with limitations in cognitive ability that is present in childhood and may contribute to reduced education level. One study observed that limited linguistic ability in young women increased the likelihood of meeting neuropathologic criteria for AD in old age (44). Developmental deficiencies may result in reduced brain development with diminished reserve capacity, which may modify lifelong patterns of growth and risk of AD (42,44).

Early development correlates of LBW include the rapid gain of weight after birth, increased central adiposity, and metabolic irregularities such as insulin resistance. As these are also important early risk factors for

type 2 diabetes mellitus, it is not surprising that connections between features of diabetes and AD pathology have been drawn. Rat models have shown experimentally that killing insulin-producing cells in the brain in early life have produced AD-like pathological features. Furthermore, in work using transgenic murine models of AD, increased intake of water supplemented with sucrose advanced amyloidosis and the appearance of cognitive deficits, while caloric restriction was found to be protective (45).

Knowledge is limited about connections between environmental exposures such as infectious and chemical agents and AD. The relationship between environmental exposures and cognitive decline has been explored in some detail, especially the role of lead exposure in reduced cognitive function. One study (46) of blood levels in 172 children showed that even blood lead concentrations below 10 µg/dL are inversely associated with children's IQ scores at three and five years of age, with declines in IQ greater at smaller than at higher concentrations, suggesting a stronger effect of environmental exposure to lead in childhood than previously estimated. Cognitive decline from lead exposure has been found to continue through development and into adulthood, as seen through consistently lower IQ levels and behavioral changes (47). Furthermore, occupational lead exposure among adults correlates with lower neurobehavioral test scores and with deficits in several cognitive spheres, including measures of executive function and verbal intelligence and memory (48). Evidence for gene–environment interactions in cognitive decline is evidenced by findings that persons with at least one *APOE* ε4 allele may be more susceptible to the effects of prolonged lead exposure on the central nervous system (49). While a direct relationship between cognitive decline from lead exposure and AD development has not been shown in humans, a primate model of early life exposure to lead demonstrated a development of AD-like pathological abnormalities in the brains of infant monkeys; however, monkeys exposed later on in adulthood did not show similar pathology (50).

Head trauma is also associated with AD, but whether trauma occurring earlier or later in life increases risk is unknown. It should be noted that adult head circumference has been observed to correlate with cognitive performance; likewise, traumatic brain injury during childhood is associated with reduced head size (42,51), suggesting that head size may mediate the effect of brain injury on AD risk.

## 111.2 GENETICS OF EOAD

Linkage analysis, followed by positional cloning of candidate genes, was used to identify genetic variants of the three genes known to cause autosomal dominant EOAD. The three known AD-causative genes are amyloid precursor protein (*APP*) (52), presenilin 1 (*PSEN1*), and presenilin 2 (*PSEN2*) (53–55).

### 111.2.1 Discovery of the *APP* Gene

The first AD-causing mutation found was in the *APP* gene. *APP* was initially cloned and localized to chromosome 21 in 1987 (56,57). Chromosome 21 was an intriguing location, since those with trisomy 21 (Down syndrome) develop the pathologic signs (neuritic plaques and NFTs) and symptoms of AD at an early age (58). Interestingly, an individual who was affected by translocation Down syndrome, but did not develop the characteristic Alzheimer dementing syndrome, was identified. On autopsy, the brain was free of the characteristic AD plaques and tangles. The individual's DNA revealed a duplication of the obligate telomeric Down syndrome region of chromosome 21, but the *APP* gene was not within this duplication (59). Within families affected by *APP* mutations, functional analyses have demonstrated the likely pathophysiologic processes causing AD. The identified missense mutations lie outside of the beta-amyloid region of the *APP* gene, and as *APP* can be cleaved into one of two amino acid sequences, these mutations appear to cause shifts in the proteolytic cleavage of *APP* toward the production of beta-amyloid ( $A\beta$ ) products. In neuroblastoma cell lines one mutation favors the production of a 42 amino acid residue-length  $A\beta$ .  $A\beta$  is a major component in senile plaques. This 42-residue beta-amyloid ( $A\beta_{42}$ ) is less soluble than the alternative 40-residue isoform ( $A\beta_{40}$ ) (60).  $A\beta_{42}$  is also associated with increased aggregation and neurotoxicity (Hilbich et al., 1991). *APP* mutations consistently show increased production and/or deposition of the pathogenic long- $A\beta$  product (60,61). The long- $A\beta$  isoforms are less soluble than the shorter  $A\beta_{40}$  isoform, and these  $A\beta$  deposits are the principal component of amyloid within the characteristic plaques of AD-affected brains (62). Transgenic mice expressing the human *APP* mutation develop senile plaques, but not the tangles, characteristic of AD (63). A second characterized mutation in *APP* causes double mutation-transfected neuroblastoma cells to secrete five times the  $A\beta_{42}$ , compared to control cells with wild-type *APP* (64). The neurotoxicity of  $A\beta$  has been well demonstrated in cell culture (65,66).  $A\beta$  also confers increased vulnerability to excitotoxic damage of hippocampal neurons in vitro (67). Furthermore, when  $A\beta$  is added to neuronal cell cultures, there is a distinct loss of synapses, analogous to the early pathologic processes of AD (68). Image analysis of  $A\beta$  load in AD patients and controls demonstrates a positive correlation between the amount of  $A\beta$  and severity of cognitive deficit.

While it was clear that some early-onset families were affected by *APP* mutations and showed linkage to chromosome 21 (69), many others were found not be affected by *APP* mutations (70,71). Worldwide, only about two dozen families have been described as carrying mutations of the *APP* gene. Among these families, at least 15 different pathogenic mutations have been characterized (Alzheimer Disease Mutation Database) (72). Therefore,

*APP* mutations that cause AD display allelic heterogeneity. Since the majority of early-onset familial AD is not caused by mutations in the *APP* gene, there is clearly locus heterogeneity for EOAD (73,74).

### 111.2.2 Discovery of the *PSEN1/PSEN2* Genes

Subsequent studies in additional families with autosomal dominant inheritance demonstrated genetic linkage to chromosome 14 (75–77). In 1995, the first AD-causing mutation in the *PSEN1* gene was identified (55). Since then, more than 150 different *PSEN1* mutations scattered throughout the gene have been described (78,79). Interestingly, the majority of the large autosomal dominant AD families appear to carry unique *PSEN1* missense mutations (Clark et al., 1995). While several families with the same *PSEN1* mutation have been identified, these families appear to be unrelated, providing evidence that the same mutation may have arisen more than once (80,81). Phenotypically, *PSEN1* familial AD is the most aggressive form of AD, and affected individuals generally have disease onset in their fourth or fifth decade of life (82). The characteristic amyloid plaques in brains of individuals affected with AD and a *PSEN1* mutation show a relative abundance of  $A\beta_{42}$  compared to the plaques in individuals with sporadic AD. Quantitative image analysis using  $A\beta_{42}$  and  $A\beta_{40}$  antibodies demonstrate a 1.5- to 3-fold relative increase in plaques containing  $A\beta_{42}$  peptides (58,83).

After characterization of *APP* and *PSEN1*, there remained EOAD-burdened families under study that did not show segregation of known mutations, and that did not link to either chromosome 21 (*APP*) or 14 (*PSEN1*). These included families originating from the Volga River basin of Russia (84) who showed linkage to chromosome 1 (53). Serendipitously, with the cloning of the *PSEN1* gene, a larger 7.5-kilobasepair (kb) alternative polyadenylation message was identified. The product represented a gene homologous to *PSEN1*. The new gene was mapped to a known linkage region on chromosome 1, and was identified as *PSEN2*. Mutations in *PSEN2* are rare, but have been described in the Volga River basin families and in one Italian pedigree (53,54). Individuals affected by *PSEN2* mutations have a variable time to disease onset, ranging from the fourth through the eighth decade of life.

### 111.2.3 Pathophysiologic Roles of *APP* and the Presenilins

The physiologic role of the presenilins remains unclear. However, the presenilin mutations do appear to have a pathophysiologic relationship with *APP*. Assays of  $A\beta_{40}$  and  $A\beta_{42}$  in the plasma and the cultured skin fibroblast media of individuals with presenilin mutations revealed a twofold elevation of  $A\beta_{42}$  levels, despite no mutations of

the *APP* gene (85). In addition, transgenic mice expressing *PSEN1* and *APP* mutations demonstrate A $\beta$ <sub>42</sub> plaques and an accelerated AD-like phenotype (86). These observations pointed to an interaction between *APP* and the presenilins. Whether the presenilins interact directly with *APP* through their putative  $\gamma$ -secretase activity, or act as cofactor for another  $\gamma$ -secretase, remains unclear; however, it is clear that, like *APP* mutations, the *PSEN1* and *PSEN2* mutations all lead to increased levels of A $\beta$ <sub>42</sub>. The precise role of A $\beta$  accumulation in the pathogenesis of AD remains under investigation. A $\beta$  accumulation may be the final common neurotoxic pathway, an additional toxic by-product of the primary neurotoxic pathway, or less likely, an inert by-product (79).

Variants in these three genes (*APP*, *PSEN1*, and *PSEN2*) account for between 30% and 50% of early-onset familial AD (87), yet together they account for less than 2% of all cases of AD (88–91). In addition, while the genetics underlying autosomal-dominant or familial EOAD may appear to be relatively straightforward, the variants in genes responsible for AD in many families have yet to be characterized. Furthermore, the relationship between identified causal mutations and AD phenotype is not necessarily simple. For example, *PSEN1* mutations associated with familial EOAD have been identified in individuals with frontotemporal dementia who have no evidence of the A $\beta$  accumulation characteristic of AD (92,93). Nevertheless, each gene discovered has contributed to the elucidation of the pathophysiologic mechanisms underlying AD.

### 111.3 GENETICS OF LOAD

LOAD cases comprise the majority (90–95%) of individuals afflicted with AD. The prevalence of LOAD increases exponentially with advancing age (5). LOAD also increases the risk for other major common disorders (e.g. cardiovascular and cerebrovascular diseases), which reduce life expectancy (94,95). Thus it is clear that LOAD has a significant negative impact on the quality of late life and will represent a major financial and emotional burden to society until effective treatments or preventions are available.

There is compelling evidence that the etiology of LOAD, like EOAD, is also strongly genetic. Family studies (96,97) and twin studies (36,98) have suggested that LOAD may aggregate within families. While the majority of LOAD cases are sporadic, 15–25% are familial (99). Segregation analyses suggest the inheritance of LOAD is consistent with Mendelian inheritance, with incomplete penetrance and an additional multifactorial component (38,40).

Despite strong evidence that LOAD is a genetic disease, the complex etiology of LOAD still poses a great challenge for the identification of susceptibility genes. The presence of co-occurring psychiatric disorders, such as depression, varies from case to case, suggesting the

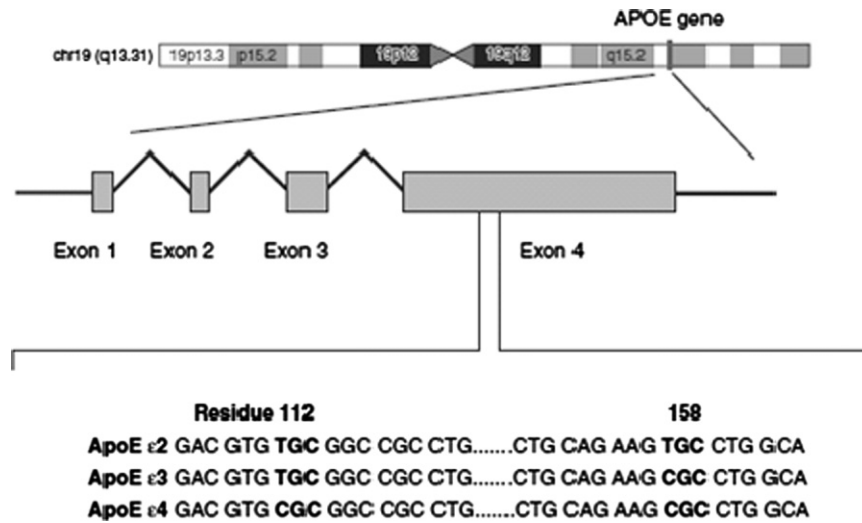

possibility of heterogeneity in disease etiology. Whether environmental exposures like lead and socioeconomic factors like access to education that factor into risk of disease interact with genetic causes of LOAD remains unclear, and gene–environment interactions may factor into the complex portrait of genetic susceptibility to LOAD.

#### 111.3.1 Discovery of the Apolipoprotein E Gene

The Apolipoprotein E (*APOE*) gene is the first and most widely accepted susceptibility gene for LOAD. It was initially discovered using affected relative pair linkage analysis in a subset of individuals diagnosed with AD at age 60 or older (100), and the signal was further refined by follow-up association analysis (101). The *APOE* gene lies on the long arm of chromosome 19 (19q13.2) (102,103) adjacent to another apolipoprotein gene (*APOC1*), and is also linked to the *APOC4*, *APOC2*, and *TOMM40* genes (104,105). *APOE* comprises four exons and three introns, spanning approximately 3.7 kb (102,106). It encodes the serum protein apolipoprotein E (ApoE), which is involved in the transport, storage, and metabolism of lipids and is synthesized in the central nervous system by astrocytes (107). There are three isoforms for ApoE protein: ApoE2, ApoE3, and ApoE4. These three isoforms result from single amino acid substitutions at residues 112 and 158 (108,109). The ApoE2 isoform is produced when the amino acid sequence contains cysteine at both residues 112 and 158. ApoE3, the most common isoform, contains cysteine at residue 112 and arginine at 158. The ApoE4 isoform is seen when the sequence contains arginine at both these two residues. These three isoforms are, therefore, produced by three different combinations of codons at the two loci: TGC (for cysteine) and CGC (for arginine), which result in three different alleles:  $\epsilon$ 2,  $\epsilon$ 3, and  $\epsilon$ 4 alleles (Figure 111-1). The frequencies of these three alleles are estimated to be 8, 78, and 14%, respectively, in most Caucasian populations (110). Other *APOE* alleles (such as  $\epsilon$ 1,  $\epsilon$ 5, and  $\epsilon$ 7), and therefore the ApoE isoforms they encode, are extremely rare in most populations. The *APOE*  $\epsilon$ 4 allele carries the strongest risk of any genetic variation for a complex disorder, and acts in a dose-dependent fashion (111). As such, the *APOE*  $\epsilon$ 4/ $\epsilon$ 4 genotype has a very high penetrance. Furthermore, the *APOE*  $\epsilon$ 2 allele appears protective for LOAD (112,113).

##### 111.3.1.1 Epidemiologic Features of the *APOE* Gene.

**111.3.1.1.1 The *APOE* Polymorphism Is Associated with Risk and AAO of LOAD.** While the role of *APOE* in cardiovascular diseases has been well characterized (114,115), its role in neurodegenerative disease has been the focus of investigation for over two decades. The  $\epsilon$ 4 allele has consistently been associated with risk for both sporadic and familial LOAD (111). In populations of European ancestry, the relative risks of LOAD for  $\epsilon$ 4

**FIGURE 111-1** Structure of the *APOE* gene and three ApoE isoforms.

homozygotes and for  $\epsilon 3/\epsilon 4$  heterozygotes are approximately 15 and 3, respectively, compared to  $\epsilon 3$  homozygotes (116). The  $\epsilon 4$  allele has the greatest impact on risk for AD among individuals who are between the ages of 60 and 79 years. Its effect is gradually attenuated as an individual surpasses age 80 (116,117). In contrast to the  $\epsilon 4$  allele, the  $\epsilon 2$  allele is protective for risk of LOAD with a reduction in risk of up to 20% (112,113,118).

The *APOE* polymorphisms also modulate the AAO for both familial (111,119–122) and sporadic forms of AD (123–125). The *APOE*  $\epsilon 4$  allele has a dosage effect on AAO. In one family-based study, the estimated mean AAO for subsets consisting of individuals carrying no  $\epsilon 4$  allele, one copy of  $\epsilon 4$  allele, and two copies of  $\epsilon 4$  alleles, were 84.3, 75.5, and 68.8 years, respectively (111). In addition, the effect of  $\epsilon 4$  allele on risk for LOAD is also age dependent. Although the *APOE*  $\epsilon 4$  allele appears to determine when an individual develops the first dementia-related symptoms, it remains arguable whether the  $\epsilon 4$  allele hastens disease progression. Two population-based studies reported that the *APOE*  $\epsilon 4$  allele was associated with a higher rate of memory deterioration in nondemented individuals (126,127). However, there is equivocal evidence regarding whether the *APOE*  $\epsilon 4$  allele speeds up (128,129) or slows (130,131) down disease progression in LOAD patients. Other studies report that the *APOE*  $\epsilon 4$  allele has little effect on disease progression (132,133).

**111.3.1.1.2 The Effect of *APOE* Polymorphism May Vary by Race/Ethnicity.** Although the *APOE*  $\epsilon 4$  allele is a risk factor for LOAD in nearly every population, the magnitude of association between the  $\epsilon 4$  allele and LOAD may vary by ethnicity. A weaker effect of the *APOE*  $\epsilon 4$  allele on risk of LOAD in African-Americans, compared with Caucasians, has been reported in several studies (134–136). A meta-analysis of 40 studies by Farrer and colleagues (116) found that the *APOE*  $\epsilon 4$  allele has less influence on risk among African-American and

Hispanic populations, compared with the Caucasian population, while the effect of *APOE*  $\epsilon 4$  allele was greater within the Japanese population. In addition, heterogeneity in *APOE*  $\epsilon 4$  allele effect size has been noted across studies of African-Americans (116) and Hispanics (137), suggesting that the effect of *APOE* on LOAD risk may depend on additional population-specific characteristics.

Variation in the magnitude of association between the *APOE* polymorphism and risk of LOAD may also reflect the variation in distributions of *APOE*  $\epsilon 4$  alleles in different racial/ethnic groups. For example, the *APOE*  $\epsilon 4$  allele frequency in cognitively normal individuals was significantly greater in the indigenous Australian population than in the Caucasian population (138). Another example from a study of three distinct ethnic groups in Malaysia showed that the *APOE*  $\epsilon 4$  allele frequency in the Indian population was higher compared to the Chinese and Malay populations (139). The “thrifty gene hypothesis,” initially proposed to study genetic mechanisms of type 2 diabetes (140), may also explain why high *APOE*  $\epsilon 4$  allele frequency does not lead to increased  $\epsilon 4$  allele-associated LOAD risk in some populations. High *APOE*  $\epsilon 4$  allele frequency in some indigenous ethnic groups may result from selection favoring the  $\epsilon 4$  allele because of its association with enhanced cholesterol uptake in environments where food supplies are more limited (141). Such a high *APOE*  $\epsilon 4$  allele frequency may not result in an increased risk of AD in these populations until more individuals start to consume a high cholesterol diet (142). The hypothesis may be supported, at least in part, by the findings of no association between the *APOE*  $\epsilon 4$  allele and LOAD in eastern Africa (143,144), while the *APOE*  $\epsilon 4$  allele is a well-established risk factor for LOAD in African-Americans (116,134–136).

**111.3.1.1.3 The Effect of *APOE* Polymorphism May Vary by Gender.** Female individuals have a 1.5- to 3-fold higher risk of LOAD compared with male individuals (reviewed in (145)). The gender effect on LOAD risk

appears to be most marked among individuals carrying two copies of the *APOE*  $\epsilon 4$  allele (116). Since estrogen is a putative neuroprotectant (reviewed in (146)), some have speculated that the higher risk of LOAD in women may be attributed to “estrogen deprivation” after the age of menopause; however, studies examining the protective effect of estrogen replacement therapy on cognitive function have produced inconsistent and sometimes contradictory findings. Inconsistencies may be due to the different study designs (e.g. observational studies versus prospective randomized clinical trials), and may relate to issues of treatment, such as timing of initiation of the therapy and type of therapy (147). The *APOE* polymorphism may also modulate the effect of estrogen on risk of LOAD. Decline in cognitive function is slowed by estrogen replacement therapy, particularly in women carrying no *APOE*  $\epsilon 4$  alleles (148). These lines of evidence suggest interactive effects between *APOE*  $\epsilon 4$  allele and gender and/or estrogen on development of LOAD.

**111.3.1.2 The Role of *APOE* on the Neuropathology of LOAD.** The definite diagnosis of AD is established based on neuropathological findings, including amyloid plaque, intracellular NFTs, and neuronal loss (149). In addition, cerebral amyloid angiopathy (CAA), defined by the accumulation of fibrillar  $A\beta$  in cerebral blood vessels, is also commonly seen in AD patients (150,151). The *APOE* polymorphisms are thought to influence LOAD risk through these amyloid-related neuropathological processes.

**111.3.1.2.1 Amyloid Plaque and NFTs.** Several studies report that individuals carrying two copies of *APOE*  $\epsilon 4$  alleles have a higher amyloid plaque density than individuals carrying one or no *APOE*  $\epsilon 4$  alleles (152–157). Two other studies did not confirm this finding (158,159). Similarly, there have been conflicting findings regarding whether the *APOE*  $\epsilon 4$  allele is associated with the density of NFTs. Several studies have reported an association between the *APOE*  $\epsilon 4$  allele and NFT density (153,156,160,161), but these have been refuted by other studies (154,157–159,162).

**111.3.1.2.2 Cerebral Amyloid Angiopathy.** CAA is present in more than 90% of individuals affected with LOAD. There is an association of CAA and the *APOE*  $\epsilon 4$  allele (156,163–165), and there is a dose-response relationship between the *APOE*  $\epsilon 4$  allele and the extent of CAA (163,166); however, a recent study has shown that *APOE* polymorphisms have no effect on the severity of CAA (Tian et al., 2004). Interestingly, although CAA is a risk factor for lobar cerebral hemorrhage, *APOE*  $\epsilon 2$  allele carriers have a higher rate of such hemorrhage related to CAA, compared with individuals carrying no *APOE*  $\epsilon 2$  alleles (167,168). This counterintuitive finding is likely due to the association of the *APOE*  $\epsilon 2$  allele and microangiopathic changes (e.g. fibrinoid necrosis and concentric splitting) occurring at the vessel wall (169).

**111.3.1.3 The Relationship of the *APOE* Gene with Anatomic Findings in LOAD.** The typical anatomic pathological change in brains of LOAD individuals is

whole brain atrophy. The medial temporal lobe, and in particular the hippocampus, manifests some of the earliest and most marked atrophy. Mild cognitive impairment (MCI) is generally understood to be an intermediate stage between the cognitive changes of normal aging and the serious cognitive declines related to AD. MCI is more likely to progress to AD in the presence of hippocampal atrophy (170). Several studies have shown that hippocampal volume is inversely associated with the number of *APOE*  $\epsilon 4$  alleles (171–173), but this finding was not supported by a different study (174). Other research has shown that the *APOE*  $\epsilon 4$  allele hastens hippocampal atrophy in nondemented individuals (175). In addition, the *APOE*  $\epsilon 4$  allele appears to exert a greater effect on hippocampal atrophy in women than in men (176).

The mechanism by which *APOE* polymorphisms influence risk and AAO in LOAD is yet to be uncovered. Several hypotheses have been posited, mostly centered on the relationship between the *APOE* polymorphisms and  $A\beta$ . One widely tested hypothesis proposes that the *APOE* polymorphisms may have an impact on the production, distribution, and clearance of  $A\beta$ . Supporting this hypothesis, the *APOE* polymorphisms influence AAO, particularly in individuals carrying the  $\beta$ -amyloid precursor protein ( $\beta$ APP) Val717Ile mutation, suggesting a possible interaction between the *APOE* gene and the *APP* gene (122). The density of  $A\beta$  peptide plaque is greater in individuals carrying at least one copy of the *APOE*  $\epsilon 4$  allele, compared to individuals carrying no copies of the *APOE*  $\epsilon 4$  allele (156). In addition, the hippocampal atrophy resulting from neuronal loss may, at least in part, stem from an impaired ability to clear extracellular  $A\beta$  due to the *APOE*  $\epsilon 4$  allele (177).

An alternative hypothesis proposes that the *APOE* polymorphisms influence risk of LOAD by altered cholesterol metabolism. Intracellular cholesterol availability impacts transport and storage of  $\beta$ APP, and therefore the reduction in intracellular cholesterol may lead to decreased  $A\beta$  formation (178). The cholesterol hypothesis is supported by observations that taking statin drugs to treat hypercholesterolemia may decrease risk of LOAD (179–183); however, a longitudinal community-based study refutes this finding (184).

## 111.3.2 Additional Candidate Susceptibility Loci for Late-Onset AD

**111.3.2.1 Overview.** While *APOE* is critically important, it does not account for all the genetic variations observed in AD. More than a third of AD cases do not have a single *APOE*  $\epsilon 4$  allele. The sibling relative risk ( $\lambda$ ) for the *APOE* locus is estimated to be about two, suggesting that *APOE* accounts for, at most, 50% of the total genetic effect in AD (116,123,185). To date, efforts to identify the remaining AD loci have taken several forms: regional and whole-genome scans for linkage in multiplex families, association tests of

candidate genes, the combining of findings across multiple studies through linkage and association meta-analyses, genome-wide association studies (GWAS), and the emerging technology of deep resequencing.

**111.3.2.2 Linkage Analysis.** Genome-wide linkage scans (GWLS) for LOAD have been published on many independent datasets since 1997 (137,186–195). Many of the scans (186–191) have focused on Caucasian families from the general population, while other scans have focused on special populations (137,189,190,193) or very large single inbred families (192,194,195). All these studies have used microsatellite markers with, at best, an average spacing of 8 cM. Some chromosomal regions have been studied extensively (most notably chromosomes 9, 10, and 12), although no consistently replicated AD gene has yet been identified within these regions. It should also be noted that while the majority of linkage

follow-up studies have focused on these chromosomes, there are numerous other linkage regions identified in more than one study that have been virtually ignored (Table 111-2).

For several reasons, reliance solely on linkage data has produced limited results and problematic inconsistencies across studies (196). One reason is that linkage analysis is more powerful than association analysis for identifying rare, high-risk disease alleles, but association analysis is more powerful for detecting common disease alleles conferring modest disease risk (197). Yet another explanation is that criteria for suggestive linkage may allow for too many false-positive regions; because of multiple hypothesis testing considerations, it is suggested that fine-mapping suggestive linkage peaks is only sensible when there is clear evidence for an excess of suggestive linkage across the genome (198).

**TABLE 111-2 Genetic Classification of Alzheimer Dementias**

Type	Chromosome	Gene
<b>I. The Alzheimer diseases</b>		
A. Early-onset familial, autosomal dominant mutations (AD1)	21	<i>APP</i>

In linkage studies of AD, initial dataset sizes were quite small and had inadequate power to detect all relevant loci. While the datasets have subsequently increased, the microsatellite marker sets have recovered less than 50% of the potential linkage information in the families (199). Thus, many regions of true linkage may remain undetected, and false-positive results may have been inflated. Even under the best of circumstances, the regions identified through GWLS still contain hundreds of locational candidate genes. Thus, while GWLS data have been, and will continue to be, useful, they do not represent a definitive, comprehensive, nor sufficiently detailed examination of the whole genome. Despite these caveats, considerable analyses have been done following up GWLS regions without confirmation of new genes identified.

### 111.3.2.3 Candidate Gene Association Analyses.

The candidate gene approach for identifying susceptibility genes focuses on specific candidate genes selected because of their known (or more often, hypothesized) biological function relevant to AD. Hundreds of genes have been individually tested for association with LOAD, and nearly 150 genes have been reported to be associated, but few of these have gained wide acceptance (200,201). There are several reasons for this. First, our knowledge of gene function is still very limited, and it has been difficult to make direct observations of altered gene function or expression in Alzheimer tissues. Second, the sample sizes and single-stage study designs have generally been too small for the small-to-moderate effect sizes and locus heterogeneity that we now suspect underlie AD. Third, the use of clinical details and clinical subtypes to define clinical (and by proxy, genetic) heterogeneity has only recently been recognized, and only sporadically implemented. Fourth, the level of genomic detail that could be interrogated was low. All these issues conspire to make replication of any true effect difficult, and false-positive results rampant. Thus, while some of these reported associations could be and are real, it is not surprising that the evidence for these loci has been mixed. Meta-analyses and GWAS are two association approaches that have been used to overcome the limitations of the candidate gene approach for identifying genes, the first by combining statistical power to detect effects across multiples datasets, and the second by interrogating most of the genome agnostically with high-density coverage.

**111.3.2.4 Candidate Gene Meta-Analyses.** Given the limitation that sample sizes in candidate gene study designs have generally been too small to detect small-to-moderate effect sizes, one approach that benefits from the availability of genetic data in multiple samples is meta-analysis. A meta-analysis by Bertram et al. (201) served not only to catalog association results across many candidate gene association studies in the AlzGene database, as described before, but also to identify associations with AD by systematically combining data on genetic variants that had been genotyped commonly across multiple studies. This study performed meta-analyses systematically

on variants genotyped in three or more samples and identified variants with small-to-modest effect sizes in 13 candidate genes for further investigation (including *ACE*, *CHRNA2*, *CST3*, *R1*, *GAPDHS*, *IDE*, *MTHFR*, *NCSTN*, *PRNP*, *PSEN1*, *TF*, *TFAM* and *TNF*).

*PSEN1* is one particular gene known to be involved in familial, EOAD, suggesting that this approach may have identified valuable candidates for further examination. The authors noted a major limitation of this approach: candidate gene studies tend to examine genes with hypothetical functional roles in disease or proximity to strong linkage signals, and this has the potential to introduce bias from several sources into meta-analytic examinations. This limitation is partially addressed by the introduction of GWAS, which deal with several potential biases by examining high-density genotyping of markers capturing most common variations across the genome, reducing overrepresentation of variant data from particular genomic regions. The application of meta-analytic approaches to GWAS data represents an additional improvement upon meta-analysis in candidate genes by improving sample sizes and allowing for small-to-modest effects to be observed with fewer potential biases inherent, provided appropriate adjustment is made for differences between high-density genotyping platforms and for relevant issues of study design.

### 111.3.2.5 Genome-Wide Association Analyses.

More than 13 studies have tested association with LOAD on high-density, genome-spanning panels of SNPs. Grupe et al. (202) pooled samples and tested association with more than 17,000 gene-based putative functional SNPs across the genome, finding a signal at *APOE* that reached study-wide statistical significance, with multiple weaker associations observed elsewhere, many occurring in regions of known linkage. Coon et al. (203) reported results of association with half-million SNPs across the genome genotyped on over 1000 histopathologically verified AD cases and controls, identifying only *APOE* as a major susceptibility gene. A follow-up study (204) stratifying cases by *APOE* genotype detected strong associations with *GAB2* SNPs, and in follow-up work observed altered *GAB2* transcript levels in vulnerable neurons, and an effect of *GAB2* levels on tau phosphorylation; replication studies have observed mixed results (205–209). Abraham et al. (210) genotyped approximately 550,000 SNPs in more than 1000 pooled cases and 1200 pooled controls, and in testing genetic associations, observed genome-wide statistical significance only for SNPs in or near *APOE*. Following up on the strongest signals that did not attain statistical significance with more individual genotyping identified the gene *LRAT* (MIM:604863), which is involved in the vitamin A (retinoid) cascade, a system previously implicated in AD. Bertram et al. (211) analyzed 500,000 SNPs in 410 families, reporting an SNP associated with AD AAO on chromosome 14q31, and providing additional evidence of associations near *APOE* and near *GAB2*.

Beecham et al. (212) reported a GWAS on approximately 550,000 SNPs in nearly 500 AD cases and 500 cognitive controls. This study confirmed associations at *APOE* and identified an SNP on chromosome 12q13 meeting a genome-wide statistical significance threshold corresponding to a false-discovery rate (FDR) < 0.20. The strongest signals with less than genome-wide statistical significance in this study were identified in regions with prior linkage evidence, suggesting that some of these are likely to underlie true associations (213). A GWAS (214), genotyping 314,000 SNPs on 844 cases and 1255 controls, once again verified *APOE* associations, and in second-stage replication analysis, identified a novel signal on the X chromosome (combined  $P = 3.9 \times 10^{-12}$ ) in the gene *PCDH11X* (MIM:300246), encoding a protocadherin, a cell-cell adhesion molecule expressed in the brain. Finally, a study (215) using the original set of cases and controls from Beecham et al. (212) and additional newly identified cases and controls with high-density genotyping examined associations in a genome-wide set of markers (483,399 SNPs) and identified an association with LOAD of genome-wide significance ( $P = 4.70 \times 10^{-8}$ ) at 151.2 Mb of chromosome 6q25.1 in the gene *MTHFD1L*, which encodes the methylenetetrahydrofolate dehydrogenase (NADP+ dependent) 1-like protein, a gene involved in the pathway synthesizing methionine from homocysteine, and thus may influence homocysteine levels, known risk factors for AD.

While many of the aforementioned non-*APOE* associations attained genome-wide significance and were found to be associated in replication datasets, associations of these variants have not been found to be statistically significant in other independent studies, and for this reason, it remains unclear whether these genetic variations are truly associated with risk. A notable limitation of these studies is the lack of statistical power to detect small or even modest associations (odds ratio (OR) < 1.5) with samples sizes of ~1000 cases and ~1000 controls, or less. A second generation of GWAS with greatly increased sample sizes were able to detect the first set of associations of variants with small effects on LOAD and that replicated in multiple studies. The first of these by the European Alzheimer Disease Initiative (EADI) (216) examined associations in a total of 6010 LOAD cases and 8625 controls, and observed highly significant associations in *CLU*, a chromosome 8 p21.1 gene that encodes clusterin or apolipoprotein J, and in *CR1*, a chromosome 1q32.2 gene encoding the complement component (3b/4b) receptor 1. Effect sizes for associations of the minor alleles at these loci were either slightly deleterious (for *CR1*, OR = 1.21) or slightly protective (for *CLU*, OR = 0.86). The Genetic and Environmental Risk in Alzheimer Disease (GERAD) consortium (217) also observed genome-wide statistical significance for associations of non-*APOE* genomic variants in their independent dataset including a total of 5964 cases and 10,188 controls. These included strong associations in *CLU* (OR = 0.86),

one of the genes with significantly associated variants in the Lambert et al. study, and novel associations in the *PICALM* gene (OR = 0.86). A third study by the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium (218), which incorporated data from both the EADI and GERAD consortia to investigate an overall 9511 cases and 28,174 controls, identified associations with genome-wide statistical significance adjacent to two sets of previously unreported loci, near *BIN1* on chromosome 2q14.3 (OR = 1.13) and near *EXOC3L2/BLOC1S3/MARK4* on chromosome 19q13.3 (OR = 1.18). *BIN1* encodes the bridging integrator 1 protein, which is a nucleocytoplasmic adaptor protein that is heavily expressed in brain and muscle. Of the three genes proximal to the significant associations on chromosome 19q13.3 (signals that are independent of and not in linkage disequilibrium with associations in the *APOE* region), only two are potential biological candidates involved in AD-related pathways: *BLOC1S3*, which encodes subunit 3 of the biogenesis of lysosomal organelles complex-1 protein, influences endosomal to lysosomal routing, and is expressed in the brain; and *MARK4*, which encodes the MAP (mitogen activated protein)/microtubule affinity-regulating kinase 4 protein, is expressed exclusively in the brain, and participates in neuronal differentiation.

Most recently, two even larger GWAS, one from the Alzheimer Disease Genetics Consortium (ADGC) (219) and another from a joint GERAD/EADI/CHARGE analysis (GERAD+) (220), confirmed the genetic associations at *CLU*, *CR1*, *PICALM*, and *BIN1*, and further identified and confirmed several additional AD susceptibility loci. The ADGC examined data on nearly 2.5 million genotyped and imputed SNPs from 11,840 cases and 10,931 controls in 15 datasets using a three-stage design, all on samples from individuals of European ancestry. These novel SNP associations with LOAD at *MS4A4A*, *CD2AP*, *EPHA1*, *CD33*, and *ABCA7* bring the total of consistently replicated loci associated with LOAD risk to 10 (*APOE*, *CR1*, *CLU*, *PICALM*, *BIN1*, *EPHA1*, *MS4A*, *CD33*, *CD2AP*, and *ABCA7*), confirming the emerging consensus that common genetic variation plays a significant role in the etiology of LOAD. These two studies estimated that, with the inclusion of genetic effects contributed by the nine non-*APOE* loci, as much as 50% of the genetic effect of LOAD may now be explained.

The next generation of genetic studies will likely take several forms. Some will combine and meta-analyze findings from large GWAS consortia, and with the increase in sizes of these datasets to many tens of thousands of LOAD cases and controls, much greater power will be available to identify and replicate newfound genetic associations with LOAD, and to uncover the biological mechanisms underlying disease pathology. Others will integrate annotation data on biochemical pathways to perform associations of variants at multiple related loci

through pathway analyses, while still others will integrate data on important biomarkers like A $\beta$  in order to be able to capture genes more closely related to specific pathological features of disease.

### 111.3.3 Clinical Implications of Genetic Discoveries for AD

**111.3.3.1 Genetic Counseling and Testing.** Increased media attention and access to genetic testing through clinical laboratories and direct-to-consumer testing have enhanced public awareness of the role genetic factors play in the etiology of AD, but the personal and clinical utility of such information has thus far been unclear. It remains controversial whether genetic testing for AD is appropriate, particularly since effective treatments and preventions for AD are still lacking (88,221,222). In light of these facts, the National Society of Genetic Counselors and the American College of Medical Genetics published practice guidelines for clinicians to assess their patients' risk for AD, to determine when genetic testing is appropriate, and to counsel their patients accordingly (223).

Using information collected from a three-generation pedigree, risk should be assessed based on average AAO in the family (early or late onset) and pattern of inheritance observed (sporadic, familial, or autosomal dominant). Genetic counseling should include information about the patient's risk relative to the population and the current status of treatment and prevention options. For families in which an autosomal dominant form of AD is a possibility, it is recommended that genetic testing be offered for causative forms of dementia using the *Guidelines for Genetic Testing for Huntington's Disease (HD)* set forth by The Huntington's Disease Society of America (224). In particular, pretest genetic counseling should include a discussion about the likelihood of identifying a mutation in the family and, if so, risk to the patient and offspring, motivations and considerations for pursuing testing, permanence of the information, and the potential impact of insurance, psyche, life plans, and relationships, among others. Genetic testing for causative mutations in a referral-based series of AD cases was proved to be cost-effective (225), and when accompanied by appropriate genetic counseling, resulted in effective coping skills and absence of untoward psychological responses (e.g. severe depression, anxiety, or suicidal ideation) (226–230).

On the other hand, while guidelines recommend assessing and counseling about risk, genetic testing for those with familial or sporadic LOAD is not recommended in most instances. In addition to a lack of clinical utility for those who carry APOE  $\epsilon$ 4 allele(s), APOE testing has low sensitivity and specificity, and it is difficult to convey probabilistic risk based on the presence or absence of an  $\epsilon$ 4 allele (231). Based on data from the REVEAL study, which suggest that APOE testing

on a self-selected, highly motivated, and educated group does not result in significant short-term psychological distress, guidelines further state that testing may be considered at the clinician's discretion if the patient wishes to pursue testing despite genetic counseling and recommendations to the contrary (232). In such instances, the same testing protocol used for causative genes should be used.

**111.3.3.2 Pharmacogenomics.** Genetic information may help illuminate disease mechanisms and facilitate developing targeted treatments. Diverse genetic influences in AD may drive biochemical pathways that result in the clinical heterogeneity observed in AD. Therefore, individuals affected with different subtypes of AD or other dementias may be characterized by different disease courses, prognosis, and responses to treatments. Pharmacogenomics research may shed some light on heterogeneity in individuals' response to pharmaceutical compounds.

Donepezil, galantamine, rivastigmine, and tacrine are cholinesterase inhibitors (ChEIs) used to alleviate AD symptoms, with evidence of weak-to-moderate efficacy (233–235). Response to ChEIs may differ by APOE genotype (236). Specifically, carriers of at least one copy of the APOE  $\epsilon$ 4 polymorphism have been shown to be the less responsive to the ChEI tacrine (237).

The ChEIs are metabolized primarily by the cytochrome P450 drug metabolism proteins (238). Their baseline metabolic activity varies greatly from individual to individual, largely because of polymorphisms in the genes encoding them. One such polymorphism in the CYP2D6 gene has been found to contribute to 15% of cases of efficacy and/or adverse drug response in AD (239). There are ethnic and geographic differences in the frequency of these polymorphisms. For example, the CYP2A<sub>del</sub> mutation is present in 15% of Asians, but only 1% of Caucasians, and produces a protein product with no metabolic activity (240).

The clinical significance of P450 gene polymorphisms as related to response to ChEIs has not been thoroughly elucidated. Similarly, pharmacogenomic approaches to developing drug targets in AD have not been extensively utilized in clinical practice (241).

### Biographies

**Margaret A. Pericak-Vance, PhD**, is the Associate Dean for Human Genomic Programs and Director of the John P. Hussman Institute for Human Genomics at the University of Miami Miller School of Medicine. She is a genetic epidemiologist and a founding fellow of the American College of Medical Genetics and a board-certified PhD medical geneticist. She has extensive experience in many types of genetic analysis. She directs the statistical and molecular genetics screening laboratory. Her particular area of interest is identifying genetic risk factors for complex traits. She was the first to report the linkage of late-onset Alzheimer disease (AD) to chromosome 19. She was responsible for the association studies of APOE-4 and AD. It was her laboratory that first reported the dosage effect of the APOE-4 allele on both risk and age-of-onset in AD, as well as the protective effect of the APOE-2 allele.

**Jonathan Haines, PhD**, is a genetic epidemiologist, Louise B. McGavock Professor of Human Genetics, founder and Director of the Center for Human Genetics Research (CHGR), and Professor and Chief of the Division of Human Genomics within the Department of Molecular Physiology and Biophysics at Vanderbilt University. Dr. Haines has extensive experience in all aspects of genetic epidemiology including clinical ascertainment and statistical and molecular analysis. He has supervised genomic studies for many complex disorders including autism, Alzheimer disease (AD), multiple sclerosis (MS), and macular degeneration. Most recently, he has been involved in multiple genome-wide association studies (GWAS) including those for autism, AD, MS, and breast cancer.

**Susan Hahn, MS, CGC**, is a board-certified genetic counselor and the Assistant Director of Communications, Compliance, and Ethics at the Hussman Institute for Human Genomics at the University of Miami Miller School of Medicine; a Director of the American Board of Genetic Counselors; current Chair of the Public Policy Committee of National Society of Genetic Counselors (NSGC); and a member of the Practice Guidelines Committee of the ACMG. She is an author of the recent practice guidelines regarding genetic counseling and testing for Alzheimer disease. She is knowledgeable on a variety of topics related to genomic medicine including clinical discoveries, genomic education initiatives, genomic medicine tools such as family history tools and algorithms, outcome measurements, and ethical, legal, and social issues related to genomic medicine, including impact on health disparities.

**Adam Naj, PhD** is a postdoctoral associate investigating late-onset Alzheimer disease (LOAD) with Margaret Pericak-Vance at the John P Hussman Institute for Human Genomics. He has performed multiple research projects identifying genetic risk factors for LOAD and related phenotypes. These include two genome-wide association studies (GWAS) of LOAD cases and cognitive controls, including work for the Alzheimer Disease Genetics Consortium, with which he recently published a study newly identifying four genes that contribute to genetic susceptibility to LOAD. His ongoing work includes adapting existing linkage and association techniques for the analysis of next-generation sequence data on LOAD cases and controls.

**Regina Carney, MD**, is a consultant on the Hussman Institute's Alzheimer study. Dr Carney has been involved in genetic research projects in hereditary spastic paraplegia, Parkinson's disease, tuberculosis, autism spectrum disorders, and Alzheimer's disease. Having completed her clinical training in psychiatry, she has decided to focus her efforts on Alzheimer's disease. Dr Carney has participated in the Alzheimer's disease genetic study in multiple capacities, including clinical project management, achieving recruitment and enrollment goals, organizing and overseeing team efforts, participating in clinical case conferences, and managing clinical research staff.

**Michael A Slifer, MD, PhD**, is a Psychiatrist who served as the Chief Resident of Psychiatry and Behavioral Sciences at Duke University. He has research experience in Alzheimer disease genetics, and focuses on the molecular and clinical subphenotyping of genetically complex heterogeneous disorders.

## Schizophrenia and Affective Disorders

*Jonathan D Picker*

Division of Genetics, Departments of Medicine and Child and Adolescent Psychiatry,  
Children's Hospital Boston, Boston, MA, USA

### GLOSSARY

**Psychiatric disorder** – A state in which an individual's behavioral actions and state are not within the norms of their society.

**Schizophrenia** – A psychotic disorder with symptoms including hallucinations, delusions, thought processing defects, mood effects and social withdrawal.

**Affective disorder** – A disorder of emotional state that results in excessively negative and/or positive mood states, which may not be congruent to the individual's situation and which are protracted. This disorder may include swings from one state to the other and include psychotic elements.

### 112.1 INTRODUCTION

Psychiatric disorders exert a unique and profoundly negative effect on individuals, their families and society in general. Although not isolated to our species, they are often thought of as uniquely human because of their impact on the individual's personality and challenge our perceptions of what it is that constitutes a human individual (1).

Psychosis in particular has elicited contemplation, with etiological theories, and management recommendations recorded in some of the earliest written records from the Mesopotamian region (2). Indeed, extensive and diverse descriptions of psychopathology were offered throughout the ancient world (3). This is likely a result of the florid effects of this group of disorders and the fact that most members of society are, in one way or another, impacted by them. Interest not only was of an intellectual nature but also reflected the need to deal with the effects of the psychopathology, for the individual and/or society's sake.

This chapter, by focusing on classic schizophrenia, bipolar disorder 1 (BPD1) and major depressive disorder (MDD) will review current understanding of schizophrenia and the affective disorders from a genetic perspective.

The milder variants, e.g. bipolar disorder 2 (BPD2), schizophreniform disorder and other subclassifications as well as intermediate states such as schizoaffective disorder (which has elements of each of the primary disorders), are no less valid; however, understanding of these disorders is yet too tenuous to do more than complicate a field already challenged by diagnostic complexities and conflicting data. Therefore, except in so far as these diagnoses inform the classic disorders, they will not be discussed.

#### 112.1.1 Incidence of the Disorders

Almost half of all Americans are at risk for having a major psychiatric disorder at some point in their life. The affective, or mood, disorders affect one in five people in their lifetime. The prevalence of MDD accounts for 17%, and BPD (type 1 or 2) for 4%, of the prevalence, respectively. Affective disorders are the leading cause of disability in young adults (under 45 years of age) (4). Schizophrenia is reported to occur around the world with a prevalence ranging from 1.4 to 4.6 per 1000 of the population in most groups (5). There are some notable exceptions, including the significantly elevated incidence in some immigrant groups (6) as well as the significantly decreased rates found among the Hutterites of both Dakota and Manitoba (7).

The high incidence of these disorders therefore has significant implications on health, well-being and the economy; although the costs to individuals and society can be difficult to fully measure (8). It is estimated that BPD1 and schizophrenia each have annual public health costs in the tens of billions of dollars in the United States alone (9). The costs to a degree reflect the fact that management remains problematic. The reason for limited management capabilities, in part at least, is a consequence of our limited understanding of these disorders.

The human genome project may offer the first novel approach to unraveling the pathoetiology of these

disorders since ancient times and as a result has generated tremendous excitement and hope (10). In order to realize the potential of genetic research, however, it is crucial to be aware of the basic assumptions that underlie these disorders and psychiatry in general, in order to avoid simplification and misinterpretation of the data.

## 112.2 HISTORY AND DEFINITIONS OF THE DISORDERS

The primary problem facing psychiatric research and management is knowing what we are dealing with.

In order to understand what psychiatric illnesses are, it is crucial to view them from a historical context, as current understanding remains deeply rooted to previous concepts. This is evident in society's ongoing separation of the physical illnesses from the psychiatric ones, with the implication that there is something other than "physical" that underlies them. Furthermore, even within the field of psychopathology, conditions managed by psychiatrists and psychologists are defined as "disorders" or "behaviors," with the former considered to have a biological etiology, whereas the latter are considered "volitional," as, for example, cannabis use would be considered. Despite the recognition that there are underlying components to the behavior nonetheless, the supposition is that the behavior is secondary and, hence, once removed from the biology. Heritability estimates from modern twin studies, however, provide no evidence to support a differentiation of involuntary (disease) or voluntary (behavior), suggesting that mainstream psychiatric concepts remain detached from biology (11).

With respect to the etiological theories for psychiatric disorders, it appears that hypotheses are proposed that largely fit into the cultural views of the societies then extant. Thus it has been suggested that trephining holes found in the skulls of stone age people represent treatments designed to allow an escape portal for evil spirits (12). It is perhaps not surprising that preoperational, animistic and polytheistic societies develop such views. Interestingly, however, the theme of behavioral disorders occurring as a consequence of a spiritual vector re-emerged in late medieval Christian Europe. This is well described by Christian Brandt in his *Das Narrenschiff*, or "ship of fools," in which the passengers, as a consequence of their sins, were led to acts of "folly" or madness. Despite running counter to the professed free will beliefs of the society, the intelligentsia yet rationalized previous ideological systems into the framework of beliefs then current. There is no reason to believe that our society is less susceptible or that our current hypothesized etiological constructs for these disorders is less wedded to beliefs *au courant* than those of the past. This may be exemplified by the commonly accepted hypothesis that psychiatric disorders are largely multifactorial in origin; however, it has also been proposed that the fit is more semantic than data driven (13).

Regardless of potential cultural influences, observational descriptions of the psychopathology provide an additional layer of complexity. Focusing for the moment on schizophrenia, the current definition, according to the Diagnostic and Statistical Manual of Mental disorders 4th edition revised (DSM-IV-TR™) (14), includes the presence of at least two category A symptoms of delusions, hallucinations, disorganized speech, disorganized behavior and negative symptomatology, which includes flattened affect, *alogia* (poverty of speech) or *avolition* for at least 1 month coupled with a failure to maintain function in at least one domain of work, school, self-care or interpersonal relationships. Overall symptoms should be present for at least 6 months, although this time frame may include the presence of "prodromal" symptoms, e.g. odd beliefs or unusual perceptions. Fulfillment of these criteria defines one as having schizophrenia, whereas failure to do so may result in an alternate diagnosis. The subclassifications of paranoid, disorganized (hebephrenic), catatonic, undifferentiated and residual types of schizophrenia themselves have stated symptomatology required for diagnosis. Similarly, mood disorders involve characterized symptomatology that is required for a "scientifically" valid diagnosis.

A major mood disorder is classified by DSM-IV as having an at least 2-week period of depression that is not a part of bipolar disease, an underlying medical disorder or substance abuse. Depression is characterized by anhedonia or dysphoria and symptoms that may include changes in sleep, appetite, loss of sense of self-worth, guilt and suicidal ideations. BPD may or may not have a history of a mood disorder but includes a period of mania, as demonstrated by a period with expansive, persistently elevated or irritable mood, and may include increased self-esteem, grandiosity, talkativeness, distractibility, goal-oriented activity, disinhibited potentially reckless activities and decreased need for sleep. Psychotic symptomatology may be present in both disorders. Notably, the diagnosis of bipolar disease requires a diagnosis of schizophrenia to be excluded and the diagnosis of a major depression additionally requires bipolar disease to be excluded, reflecting a close relationship between the three disorders.

These diagnostic criteria are descriptive and arbitrary definitions lacking a pathological basis upon which to ground them. The field of psychiatry has been cognizant of this since the inception of these definitions and seeks to improve upon them with the DSM-V (currently anticipated for release in May of 2013). This has been in development since 1999 and is charged with expanding the scientific basis for psychiatric diagnosis. As a result, the definitions for many disorders will be changing. Schizophrenia, for example, will no longer include subtype classification. This will result in a broader overall definition of the disorder. This change in subject definition will have a knock-on effect for research, albeit the nature of this effect being unknown.

From a research perspective, however, psychiatric diagnosis, including schizophrenia and the affective disorders, have another layer of complexity. In addition to the DSM conceptualization (which is the product of the American Psychiatric Association), there coexists the International Classification of Diseases (ICD), which is supported by the World Health Organization. The ICD is a system ratified by the majority of countries in the world. While the two systems have much in common, there are differences. The ICD provides alternate diagnostic criteria for psychiatric disorders that are probably of etiological significance. For example, within the schizophrenia spectrum of disorders, DSM10 does not include schizotypal disorder like DSM, but rather places it within a personality disorder classification. In addition, individuals with medical and substance abuse specified precipitants are also not included in the schizophrenia group of disorders. At this time, it remains unclear whether these changes increase the diagnostic stringency and therefore the likelihood of finding discrete genetic factors, or exclude important groups of subjects, significantly reducing the power of population studies.

The classification issue becomes further complicated by cultural attributes, which may lend differing emphasis to elements of the diagnostic criteria as applied to different populations. This is well exemplified by the differences in categorizing catatonia depending on if one is in Wales or in India (15).

Regardless of this and of which criteria are used, the definitions of schizophrenia and the affective disorders remain mutable, and this will not change with the introduction of DSM-V or ICD 11, as each reflects the most recent iteration of consensus opinion rather than concrete objective diagnostic standards. This should not be viewed as a fault, given that we do not have sufficient understanding of these disorders to be both specific and sensitive. As far as currently possible, DSM-V is attempting to classify on an etiological basis (16). Lacking measurable criteria, these diseases must be described phenomenologically, but with awareness that what is defined may not represent discontinuous disorders with well-defined boundaries. As a consequence, research into psychiatric disorders, genetic or otherwise, is based on studies of perceived symptom clusterings and not necessarily discrete disorders.

One way to get around the difficulties involved in comparing individuals with these arbitrary and quite likely heterogeneously derived disorders is to identify endophenotypes to use as a proxy. Endophenotypes are quantifiable traits that may be chemical, anatomical or physiological and that are reliably present in affected individuals. They are considered to be biological intermediates between the underlying pathology and symptomatology, and as such, may provide greater sensitivity for the purported underlying disorder. The applicability of the endophenotype concept in psychiatry appears legitimate, although optimal candidates are lacking (17).

There are limitations because of sensitivity and specificity issues with currently identified endophenotypes, but they may still aid in second-level studies of candidate genes. For example, although the term neuroticism is used in some cases, MDD still lacks a well-agreed endophenotype (18). The options appear to be better for schizophrenia. Prepulse inhibition (PPI) of startle is recognized to be deficient in schizophrenics and their first-degree relatives (19). It is, however, also deficient in other situations, including drug usage, stress and fragile X syndrome (20). This lack of sensitivity limits its use diagnostically. PPI provides a measurable outcome for an experimental stimulus, e.g. the effect of candidate gene activity, particularly in animal models, and therefore can be very useful (21). Endophenotypes with higher sensitivity and specificity are being sought to improve experimental studies (22) and also to aid in improving diagnostic acumen. Interestingly, gene expression levels are themselves being postulated as endophenotypic measures in neurological research (23), although insufficient understanding means this is not yet an option with the neuropsychiatric disorders.

## 112.3 BIOLOGY OF THE DISORDERS

### 112.3.1 The Evolution of a Biological Perspective

Drugs heralded the approach to understanding schizophrenia and the affective disorders from a biochemical perspective. The first modern pharmacological agent proposed for these disorders was the use of lithium as a treatment for BPD1. William Hammond of New York pioneered the use of lithium specifically for mania in 1871. This likely followed both the work of Silas Mitchell, who prescribed lithium bromide for a variety of neuropsychiatric conditions from 1870, and from observations of specific European mineral wells and American “crazy waters” used therapeutically, which include lithium in their composition (24). This role for lithium continued to be explored and used, particularly among the Danish and French, but did not start to receive mainstream attention until Cade published his case series in 1949 in Australia (25). It was not until the late 1960s, however, that American psychiatrists, well behind many others, really started using the drug. Despite this long history, our understanding of how lithium exerts this effect remains unclear. Lithium inhibits the second messenger inositol pathway involved in the release of intracellular calcium in the frontal cortex and hippocampus, among other roles (26). In addition, lithium also regulates a number of other molecules, including protein kinase 3 and glycogen synthase kinase 3 (GSK3). Both are involved in signal transduction pathways in the brain. Providing an alternate pathway and possibly reducing the relevance of the inositol pathway to bipolar disease (27). Some genetic support for an inositol role is

suggested by the identification of the lithium-regulated protein, inositol monophosphate, in both the amoeba *Dictyostelium* and human cells (28). This finding may further be supported by the reported association of this gene with BPD in some families (28b,29) as well as for schizophrenia in the Japanese population (30).

Despite the early pharmacological beginnings in BPD, research into the biochemical processes underlying schizophrenia and psychiatric disorders generally received their most significant stimulus with the identification of chlorpromazine as a treatment for schizophrenia. This was recognized in Europe in 1951 but not until 1954 in the United States. The lag reflected the resistance of the psychoanalytic community, which was the arbiter of American psychiatric practice and theory at that time (31); also in 1954, iproniazid, which was under trial for tuberculosis, was found to elevate mood (32). This was confirmed in follow-up studies focusing specifically on its antidepressant role (33), although the drug's pharmacological mechanism of monoamine oxidase inhibition (MAOI) was not identified until 1963 (34). Interestingly, one of the most widely prescribed classes of drugs for depression, the tricyclic antidepressants also evolved in 1954 from the identification of the drug imipramine, a congener of chlorpromazine. Notably, all these drugs function by modulating monoamine neurotransmission. Thus, for the first time a biochemical direction from which to develop etiological clues to pathogenesis had become available for both schizophrenia and the affective disorders (35).

From these beginnings, other pharmacological agents notably mood stabilizers, selective serotonin reuptake inhibitors, atypical antipsychotic agents and others have evolved. These drugs both informed and developed out of the biochemical theories underlying these disorders. Despite this evolution, our understanding of these disorders remains limited and the biological role of these drugs is in some cases questionable (36). This is in part because of the above-discussed difficulty in providing defined measurable indices of the disorders and in part because of our limited understanding of neuropharmacological processes. The biochemical pathways implicated by drugs have different effects in different parts of the brain. These brain regions are not functionally independent, but operate within an organ system in which multiple components are involved in variably integrated ways. Furthermore, while neurons themselves are stable, their connections to other neurons are not. The brain as an organ is perhaps unique in its functional plasticity, allowing it to remodel in response to its environment. Thus, there are multiple variables co-occurring and the different factors are influenced by genetic and environmental effects (GXE) (37) to a variable degree, depending on the stage of development (38).

With respect to developmental influences, genetic control is generally greater early in development and it has been hypothesized that the very early *in utero*

environmental sensitivity may even provide an evolutionary advantage via brain response sensitizing the fetus preparatory to life *ex utero* (39). This fetal GXE interplay itself appears to have psychopathological effects. Stressors result in altered hypothalamic–pituitary–adrenal (HPA) axis functioning, and depending on the subsequent postnatal environment, may predispose toward depression, which is associated with disturbances of this axis (40). This itself may have positive competitive evolutionary advantages. Depressive elements such as fatigue would reduce energy usage in winter and times of deprivation and sadness could evoke support from the group in settings where real benefit to these emotions occurred, unlike in modern society where these are counterproductive (41). A potential confounder is, of course, a genetic predisposition to stress; however, in an elegant assay, the effects of maternal stress on *in vitro* fertilization (IVF) pregnancies, in which the implanted embryo was either related or not to the mother, demonstrated that maternal stress was associated with depression and anxiety, whereas ADHD was present only in the biologically related offspring, suggesting that the former had a less heritable component than the latter (42).

Biochemical motifs associated with schizophrenia may also have environment-dependent benefits. The level of dopamine activity in the prefrontal cortex is closely linked to schizophrenia, as discussed later. Metabolism of dopamine occurs via catechol-o-methyl transferase (COMT). The COMT gene has different polymorphisms affecting activity. Comparison of the met158Val polymorphism appears to show that those with the Val gene have better working memory under stress but poorer at baseline (43). This may indicate that there could be a competitive advantage for carriage of putative schizophrenia risk genes under specific circumstances. Extrapolating the carrier advantage concept could, at least in part, explain the enduring incidence of the disorder in the population.

### 112.3.2 Biology of Schizophrenia

It is important to recognize that schizophrenia is a consequence of antecedent factors that prime the individual for the disorder and the pathology necessary to precipitate and possibly maintain the disorder itself. The genetic and environmental factors that predispose an individual to develop schizophrenia are therefore not necessarily all the same as those that are involved in expressing the disorder.

From an etiological perspective, there is a large body of evidence pointing to the origins of schizophrenia as a neurodevelopmental disorder (44). Many of the risk factors implicated in schizophrenia appear to relate to environmental deficits in prenatal factors. These factors were originally posited as a consequence of the WWII Dutch hunger famine. Approximately 20 years after the Nazi blockade, there was a spike in schizophrenia among

individuals who were mid-late trimester fetuses to malnourished mothers at the time (45). Investigations including the Chinese great leap forward famine and others (46) have supported this initial finding. Micronutrients have been implicated to varying degrees (47). Most evidence points to low folate in combination with elevated maternal homocysteine levels in the third trimester being associated with an increase in risk of developing schizophrenia (48). Biologically this may support the glutamate hypothesis of schizophrenia wherein hypofunction of the N-methyl-D-aspartate receptor (NMDAR) is centrally involved in schizophrenia, (49) as discussed later. Hyperhomocystinemia, which can be a consequence of folate deficiency, appears to regulate NMDAR activity, which itself regulates neural crest formation in utero (50).

Iron deficiency, a very common finding in pregnancy, has also been implicated (51). This is perhaps not surprising, as some of the same nutritional deficits involved in folate deficiency would also predispose to iron deficiency. Iron is a cofactor for dopamine formation (52) as well as myelin and oligodendrocytes (53), both of which are abnormal in schizophrenia (54) and therefore there is biological plausibility. In addition, a fourfold increase in schizophrenia was seen in the offspring of Hb-deficient mothers (51) and a national Danish cohort demonstrated a dose-response of hemoglobin level to risk of schizophrenia (55). Although the cause for the anemia was not specified, iron deficiency is the most common recognized cause in pregnant women (56).

There is also a large body of evidence supporting the role of prenatal infections, inflammation and immune dysfunction predisposing an individual to neural stress, culminating in schizophrenia with immunological and brain maturation (57).

The relative role and possible interrelationships of each of these components remains unresolved. It is likely that our understanding will improve as the pathways continue to be worked out, although it is clear each of the hypothesized risk factors involves a GXE model and is neither genetically predetermined nor wholly a reflection of the environmental milieu.

Considering the disorder itself, schizophrenia appears to involve multiple disrupted neurotransmitter circuits (58) (particularly those involving dopaminergic and glutamatergic pathways). The role of dopamine in schizophrenia is supported by multiple different approaches; thus pharmacological, neurochemical, pathological, imaging and molecular studies all support a role for dopamine dysfunction (59). Striatal D2 overactivity, secondary to presynaptic stimuli and release of excess dopamine, appears to reflect the positive symptoms of schizophrenia, specifically the psychotic elements (60); indeed, this striatal dopamine excess is not present in other disorders such as bipolar disease and major depression in the absence of psychosis. In addition, prefrontal dopamine D1 levels are decreased and may be involved in the negative symptoms, including a possible learned

anhedonia secondary to an aberrant dopamine-related reward system, whereby received signals are miscued, resulting in blunted affect (61). Postmortem and genetic studies have yet to provide strong support for the dopamine hypothesis. Furthermore, extensive use of dopamine D2 targeted therapies only provide limited benefit to the majority of individuals for whom schizophrenia remains a chronic disabling condition. This implies a role for alternate pathways (62). Hypofunction of GABAergic interneurons in the prefrontal cortex and hippocampus of postmortem samples, as well as NMDA receptor hypofunction, particularly in the corticolimbic GABAergic tracts, is well characterized in schizophrenia and is supported by electrophysiological and pharmacological studies. Furthermore, the dissociative anesthetics ketamine and phencyclidine (PCP) can induce a psychosis indistinguishable from that seen in schizophrenia (63). Both drugs act by binding to and antagonizing the NMDAR, both in healthy volunteers and in schizophrenics in remission who experienced their previous unique positive symptomatology (64). NMDAR hypofunction appears to result in reduced GABAergic function in the regions seen in schizophrenia. Whether these are primary to the underlying pathology or supportive remains unclear, although a causative role may be implied via studies with clozapine. This atypical antipsychotic demonstrates unique efficacy in a subset of schizophrenics. Prescribing glycine and D-cycloserine with clozapine resulted in a worsening of effect. It appears that clozapine acts at the glycine modulatory NMDAR agonist site, causing these other coagonist agents to become, in effect, antagonistic in behavior, further implicating a direct role for the NMDAR in the schizophrenia phenotype (65).

Whether the dopaminergic or glutamatergic pathways are primary may be irrelevant, as both appear to be disrupted in schizophrenia. Therapeutic targets and candidate genes have been found in both pathways, as will be discussed later.

### 112.3.3 Biology of Affective Disorders

As mentioned earlier, disruption of the HPA axis may be a risk factor predisposing to depression. In general, however, major depression appears to be the result of a confluence of environmental and intrinsic factors interacting dynamically with altered receptive pathways and subsequent memory retrieval in response to stimuli (66). Low neuropeptide Y levels have been associated with depression, possibly via a role in decreasing activity of hypocretin, a peptide involved in arousal and appetite in the hypothalamus (67).

Being female is a well-described risk factor for depression (68); while there may also be a sexual disparity in schizophrenia with a slight preponderance toward males it is less pronounced (69) and also does not appear to be as relevant to BPD (70). The explanation for this sexual disparity is thought to be an admixture of psychosocial

environmental causes coupled with hormonal and immunological differences, possibly interfacing with the HPA axis (71). Medical disorders such as hypothyroidism, Cushing syndrome, cancers, Parkinson disease and dopamine deficiency are risk factors for depression (72). Some of these disorders clearly interact with the HPA, which appears to be dysfunctional in depression (73). This is not the only region affected by depression, however. Reductions in gray matter in the hippocampus and cortex are seen in postmortem samples, as are deep white matter hyperintensities (74), whereas activation in the amygdala is associated with dysphoria (75). Connections between forebrain regions are modulated by monoamines, the compounds targeted by the early drugs. Depletion of monoamines is insufficient to induce depression and the rapid rise secondary to treatment does not remit symptoms (76). While depression appears to have less of a genetic component than schizophrenia and less of a relationship than BPD, there are overlapping links; thus use of ketamine, an NMDAR antagonist, can reverse depressive symptoms (77). In addition, the role of peripheral molecules such as grehlin, neuropeptide Y, melanocyte stimulating hormone, and other compounds associated with arousal and activity states such as appetite remain unclear (78).

### 112.3.4 Biology of Bipolar Disorder

A comprehensive pathoetiological model for BPD is still lacking, despite treatments that are often effective. Excess dopamine appears to play a central role in symptomatology (79). It is recognized that psychostimulants such as amphetamine elevate dopamine and lead to effects very similar to mania, even in normal subjects with elevations in mood, with increased drive and less need for sleep via increasing synaptic dopamine (80), although in bipolar patients it appears that postsynaptic sensitivity, possibly via increased dopamine transporter levels, is increased rather than dopamine levels themselves (81). Reduction in dopamine production via tyrosine-free diets attenuates this effect and improves the symptoms in manic patients (82). Dopamine's action at the mesocorticol pathway appears to increase impulsivity and reward-seeking behavior, possibly regulated by the DRD2 gene (83). As mentioned earlier, dopamine may also play a role in the biology of depression (dopamine may be central to the depression of Parkinson disease and dopamine agonists can improve the depression in these patients) (84). Alleviation of depression in BPD2 patients with dopamine agonist pramipexole appears to be via dopaminergic agonist activity in the prefrontal cortex (85). Indeed, it has been suggested that the primary difference between BPD1 and schizophrenia is not that they are different disorders but rather that schizophrenia reflects additional developmental disorders (86). Both share many of the same risk factors and significant overlap in symptomatology, along with MDD, as well

as coaggregation between these disorders within families (87) that is suggested most likely to reflect shared genetics (88).

## 112.4 EVIDENCE SUPPORTING A GENETIC COMPONENT

### 112.4.1 Heritability

Perhaps the first to quantify heritability in psychopathology was Jenny Koller, who in 1895 compared psychiatric symptoms in family members of affected individuals and unaffected controls and noted that the hereditary loading was highest for psychosis (5). Comparing family members for pathological traits is, not surprisingly, a pursuit that has taken place throughout civilization. Twin studies in particular have occurred since at least the time of Hippocrates. It was not until the first decade of the twentieth century that the potential of monozygotic and dizygotic twins to separate out environmental from genetic factors was realized by Wilhelm Weinberg (89).

As a consequence of numerous twin and family studies, the heritability of these disorders has resolved, demonstrating a differential between the disorders. Depression appears to have a heritability around 37–50%, with a two- to four fold increased risk of developing MDD overall in first-degree relatives compared to the general population. This figure rises to up to an eight-fold increase for recurrent early-onset depression (90). Nonetheless, depression appears to be about half as heritable as bipolar disease, with heritability rates for BPD reported to range from 60 to 93% (88b,91), with concordance in monozygotic twins for BPD estimated at 0.67 as compared to 0.1 for dizygotic twins and first-degree relatives (9a,90c). Schizophrenia, similarly to BPD, appears to have a heritability of over 80% (92).

Overall it is clear that there is a significant heritable component for each of these disorders, but particularly BPD1 and schizophrenia. This has raised hopes that specific genes could be identified. It has proved to be more of a challenge than was anticipated, however, and the early linkage and population studies have evolved into more sophisticated and powerful genome-wide association studies (GWAS).

### 112.4.2 Molecular Studies

**112.4.2.1 Affective Disorders.** Linkage for MDD has been suggested for various chromosomal regions, including 15q25-26, 17p12 and 8p22-21.3 (93). Linkage studies led to a possible association for the NTRK3 gene in the 15q25-26 region (94). In addition, the 2q33-35 locus was raised as a possible candidate region for women with severe depression, possibly associated with the CREB gene, which interacts with estrogen receptors (95). Most recently, regions within chromosomes 2 and 17, as well as further support for the chromosome 8

locus, have been raised as having a possible association (96). Unfortunately, replication of these results has been challenging, with little support for any specific region(s) (97). The disappointment has, however, been tempered by the advent of GWAS, offering a variety of approaches to provide denser coverage of the genome. As a consequence, an increasing number of candidate genes and loci of interest have been identified. The initial meta-analysis of GWAS studies for depression identified the strongest association for APOE (apolipoprotein E), with lesser associations for variants in GNB3 (guanine nucleotide-binding protein, beta 3), MTHFR (methylene tetrahydrofolate reductase), and SLC6A4 (serotonin transporter) (98). GWAS findings also raised an association with GRM7 (metabotropic glutamate receptor 7) as well as associations with intronic markers suggested for ATP6V1B2, GRM7, and SP4. The ATP6V1B2 locus is also potentially associated with BPD (99), which is also associated with ATP6V1G1, a gene that contributes to the same molecular complex. A further GWAS association with mood disorder and GRM7 (18) noted earlier is interesting, as GRM7 is a group III metabotropic glutamatergic receptor, possibly interacting with antidepressants (100). A number of studies have suggested an association of this molecule with BPD as well as MDD (101). In addition to the GWAS polymorphism association, there also appears to be a link involving GRM7 and BPD within copy number variants (CNVs) (102).

CNVs are deletions or gains (from duplications to multiple repeats of a given sequence) that are currently testable to a resolution as small as 1 kilobase pair (kb) in size. They may include one or more genes potentially altering gene dosage. In addition, they may disrupt gene function directly by bisecting a gene, creating novel fusion products and/or affecting regulatory elements.

In depression, duplication at 5q35.1 is the first GWAS CNV variant identified for MDD. This locus includes three genes, including SLIT3, a potentially promising functional candidate, as it is involved in axon development (103). Other CNV regions of interest in affective disorders include the 3p21.1 locus. This has emerged in a number of studies to be associated with mood disorders including BPD (104,105).

With respect to BPD an increased frequency of the 3q13.3 duplication CNV has been reported. This appears to disrupt the 3' coding region of GSK3 $\beta$  (106), a bipolar candidate gene involved in the Wnt signaling pathway and sensitive to lithium, although, as is typical in the field, studies conflict on the significance of any association (107).

Linkage analysis for BPD, like MDD, has raised candidates that are not consistently replicated. Furthermore, the data are often confounded by the variable inclusion of the broader spectrum of affective disorders of BPD1, BPD2, and sometimes MDD altogether. Nonetheless, meta-analysis of 11 linkage studies implicated susceptibility loci on 6q and 8q for BPD (108).

GWAS studies have also implicated a greater number of genes for BPD than for MDD. Diacylglycerol kinase, a protein involved in the phosphatidyl inositol pathway that is targeted by lithium, has been associated (109). Similarly, the CACNA1C gene has been implicated in BPD (99,110), as have C15Orf53, ANK3 and SLITRK2. GWAS studies appear to have demonstrated a differential between Americans of European or African ancestry (111). The ANK finding as well as other candidate regions has also been demonstrated in GWAS SNP analysis of both Europeans and Han Chinese (104b,112). While these studies have limitations, they offer the possibility of identifying potential candidate genes. For example, ANK3 is a protein responsible for regulating sodium channel-dependent action potentials and may impact cognitive attentional processing, which in turn may have relevance to BPD (113). Subsequent candidate ANK3 SNP analysis for polymorphic susceptibility to BPD is further supported by studies in different European and Asian populations (114). Similarly, CACNA1A gene polymorphisms were found to be associated with anatomical and functional brain changes congruent with BPD, as well as in schizophrenic patients, and appeared to segregate to BPD patients and schizophrenics in further studies (115).

Even when there appears to be biological plausibility and other investigations such as animal studies coupled with GWAS SNP assays are suggestive of a relationship, there remains lack of clarity. For example, GRM7, Homer1 and the 2p16.1-15 region have been proposed as relevant candidates for MDD but meta-analyses have not supported the data (18,116).

In an attempt to better assess candidate genes, those strongly associated with mood disorders (BDNF, NTRK2, SLC6A4, TPH2, P2RX7, DAOA, COMT, DISC1, and MAOA) as identified from multiple studies (117) were sequenced from three separate population cohorts to determine if variants cosegregated with mood disorders. Only P2RX7 appeared to associate with both BPD and MDD, although the common alleles of SLC6A4 (also known as HTPPLR, the serotonin transporter linked polymorphic region) appeared to have an association with mood disorders (117). Further data are required to validate this study and the many others implicating these and other genes.

**112.4.2.2 Schizophrenia.** Over 4000 articles have been written on the role of genes in schizophrenia. This is twice as many as for BPD and perhaps reflects the intense interest and high expectation from this field. Indeed, the field is so active that a gene database on the Schizophrenia Research Forum (<http://www.schizophreniaforum.org>) provides systematic and regularly updated meta-analysis of genetic association studies as well as candidate genes to assist interested parties in keeping abreast of the studies.

Candidates for schizophrenia appear to have been less elusive, although work is still required to determine

if there are unifying biochemical pathways involved in all cases. Individuals with schizophrenia appear to have an increased number of CNVs relative to both the general population and bipolar patients (118,119). Many CNVs appear to be *de novo* and occur at a six fold higher frequency compared to unaffected individuals (120). Deletions and duplications in various regions have been reported from large-scale GWAS and implicated in numerous studies across ethnicities, including 1q21.1, 15q13.3, 15q11.2, 22q11.21 as well as exon-disrupting deletions in the *NRXN1* gene. In addition, duplications in 16p11.2, dup16p13.1 and 17q12 have also been reported (121). Many of these changes have also been associated with other neurodevelopmental disorders. Apart from *NRXN1*, these regions contain numerous genes, including potential candidates, such as *BCL9* in the 1q21.1 region (122), but further studies are required to conclusively determine relevance. In addition, although the odds ratios were relatively high and the data have been replicated in a number of studies, the majority of individuals with schizophrenia did not possess these changes. Characterized CNVs are present in only 3% of individuals (123). This raises the possibility that a relatively small number of genes may carry higher risk for schizophrenia in a subset of affected individuals, supportive of the “common disease, rare variant” model. Alternatively, a proportion of these CNVs may not exert a profound role. Determining the significance of a CNV involves assessing the biological plausibility of the CNV against the clinical phenotype (124). One small study of 3 monozygotic twins discordant for schizophrenia did not identify CNV variation between them (125). Although this is not surprising, given both the very small scale of the study and the monozygosity, it does raise an interesting perspective on analyzing very early somatic mutations as a source for variability (126). This applies to CNVs, which can differ in monozygotic twins with phenotypic variability (127), and, together with genomic sequencing techniques, offers the potential benefit of identifying candidate gene differences in otherwise relatively homogenous backgrounds. This approach could potentially return monozygotic twin studies to the center of genetic research.

**112.4.2.3 Candidate Schizophrenia Genes.** As implied earlier, multiple gene candidates are proposed and over 1000 genes have been studied in connection with schizophrenia-related biology; however, evidence remains limited and only a proportion of these genes are currently of high interest. Among the many genes under active investigation a small number deserve mention on the basis of possessing both biological plausibility and genetic survey candidacy.

COMT, also a BPD candidate gene (128), is of particular interest in schizophrenia given its central role in the enzymatic degradation of catecholamines including dopamine (129), a key hypothesized molecule in

the etiology and symptoms of schizophrenia. COMT, together with proline dehydrogenase (PRODH), is haploinsufficient in 22q11.2 deletion syndrome (also known as velocardiofacial syndrome (VCFS)), a genetic disorder with a 25% incidence of schizophrenia (130). Furthermore, genetic polymorphisms in COMT and PRODH are associated with morphological changes found in schizophrenic brains (131), as well as in affected individuals (132). Conflicting results of relevance with hypo-functioning alleles, specifically the COMT Val158 Met alleles (133), have confounded interpretation. More recent analysis, however, suggests that the effect of the COMT allele is epistatically regulated, and thus the genetic milieu may ameliorate potential effects (134). With respect to PRODH, this gene itself also merits serious consideration. PRODH polymorphism has been linked to schizophrenics independently (135). Key to the metabolism of proline to glutamate, haploinsufficiency potentially impacts NMDAR activation. Polymorphisms, as well as haploinsufficiency, have been associated with schizophrenics (136).

Neuregulin (NRG1) and its receptor ErbB4 are candidate susceptibility genes for schizophrenia and appear to stimulate synaptic connectivity of GABAergic interneurons (137). Furthermore, another major candidate gene for schizophrenia appears to be intimately involved with both NRG1 and ErbB4. This protein, the NR2 subunit of NMDAR is centrally involved in the development of negative as well as positive symptoms of schizophrenia. The NR2 subunit appears to share a common anchoring domain with ErbB4, with perturbations of NRG1 and the subunit potentially impacting the function of each other (138).

The identification of a chromosomal translocation that segregated with schizophrenia and related disorders in 2000 (139) created enormous excitement. This was particularly because the translocation disrupted a gene subsequently named *DISC1*, disrupted in schizophrenia 1. In the intervening time, further evidence of an association has evolved (140), although with it, the usual negative associations (141). It has also become clear that *DISC1* is not specific to this group of disorders but rather appears to be involved in neurodevelopmental processes through inhibition of GSK3 $\beta$  activity of the Wnt1 pathway involved in cortical neurogenesis (142). It would appear that *DISC1* may be involved in the developmental predisposition, rather than concurrent pathology of schizophrenia.

### 112.4.3 Overview of the Genetic Data

Although numerous candidate genes of interest have been identified for all three disorders, of the 50–90% heritability identified for these psychiatric disorders, less than 2% appears to be attributable to the identified candidate genes. It has been suggested that epigenetic and post-transcriptional modifications may account for some of this unexpected discrepancy (143), but to what degree

remains to be determined. The data available nonetheless provides useful directions for research but is of limited applicability to practice.

## 112.5 ROLE OF GENETICS IN CLINICAL PRACTICE

### 112.5.1 Genetic Counseling

Affected individuals and family members are concerned about the risk of inheriting or passing on affective disorders or schizophrenia. Perceptions about just how likely this is vary widely across the population. Studies suggest that people both overestimate and underestimate risk (144). While providing definitive risk figures is difficult, there is benefit in tackling family perceptions on the disease etiology, as they are often misinformed. Although people consider both genetic and environmental factors to be involved, there is often a significant sense of guilt and shame as well as blame. It appears that there is not generally strong conviction in the held views. Indeed, the counseling is of interest particularly with respect to obtaining an etiological understanding more than for the recurrence risk itself. The exception appears to be if the clients have children themselves, and even in this instance, this appears to be in hopes of being able to identify possible ameliorating factors (144). Counseling not only allows for a clarified perception but itself can provide a therapeutic effect for patient and family (145). Just as psychiatric illness carries stigma so too does genetic illness. Concern that a genetic discussion implies that the disorder is inevitable and untreatable, and may result in discrimination to the individual and their family, may need to be addressed before the counseling can take place (146). It is essential to provide accurate information, and while genetic counselors, who are the experts in providing counseling, are generally unfamiliar and uncomfortable with psychiatric issues, psychiatrists, to date generally appear to be unprepared with sufficient knowledge of genetics to provide this service (147).

Risk figures are themselves challenging to provide, as these depend on the individual circumstances. Empiric data are available (148), and provides a starting point from which specific risk figures can be extrapolated. These figures are influenced by the number of family members who are affected, age of onset of affected family members, relative number of females or males who are affected, and presence of a disorder such as deletion 22q11 syndrome in the family (148b). A careful individualized risk determination taking the various factors into account may give quite different risk to the patients/clients seeking this information. Given the potential disparity in risk figures, it is recommended that this be provided through a genetic counselor determining risk from the starting point of the a priori risk and working from there (149).

Another area where genetic counseling/analysis may be helpful is in pharmacogenetics. The identification and characterization of drug metabolizing alleles provides an opportunity to better determine appropriate dosing and indeed choice of drug(s) for an individual, based on their specific situation and their predicted response. Numerous CLIA (Clinical Laboratory Improvement Amendments) certified laboratories are offering this testing on a limited basis. The most experience right now for relevant pharmacogenetic testing is the cytochrome P450 enzyme system, which is central to the metabolism of many antidepressants (150). The role for pharmacogenetics is rapidly expanding and it is likely that care will improve significantly for both the affective disorders and schizophrenia as the relevance and utility of pharmacogenomic screening is realized.

## 112.6 SUMMARY

Family and twin studies have demonstrated a genetic basis for schizophrenia and the affective disorders. Application of the human genome project has generally been disappointing, perhaps more so for these disorders (and the rest of the psychiatric field) than any other area in medicine. While this may support the notion that psychiatric disease and possibly with it, the psyche, is unique and not subject to the same rules as the rest of biology, it is too early to make such pronouncements. Limited data appear to be emerging. Evidence for candidate genes is increasing, raising the possibility that, while no one gene or group of genes will likely dominate the risk for schizophrenia or the affective disorders, the roles of the many candidates will clarify the pathways involved in these disorders. The ability to determine the steps necessary to develop the disorders will provide further therapeutic targets that may be of direct relevance to individuals for whom the genetic evidence is scant but who nonetheless may be predicted to have unidentified perturbations in pathways, or in whom consolidation of pathways may help counter undefined defects. Thus, it may not be necessary to have a comprehensive explanation for a disorder that potentially has as many paths to symptomology as there are individuals affected by the disorders. The identification of themes rather than specifics may be sufficient to improve treatment.

The inability to develop a comprehensive genetic overview also forces us to question our understanding of the relationship of the genome to cellular function in the brain. This is already starting to evolve into a search for new etiological frameworks that may ultimately help us to understand brain function at a new level. It may be that the current challenges in preventing a simplified mechanistic theory from evolving is ultimately fortunate.

### Biography

Jonathan Picker is a geneticist focused on the interface between genetics and psychiatry, particularly from a developmental perspective. Following medical school in Aberdeen, Scotland he pursued behaviorally oriented pediatrics training in Newcastle upon Tyne, England. While at Newcastle University he also carried out Masters in Biochemistry and Genetics followed by a PhD in the Faculty of Agriculture investigating molecular regulatory mechanisms. This was followed by further training in clinical genetics and child and adolescent psychiatry at the Boston Children's Hospital (BCH), where he has remained since. At BCH his clinical work has specialized in the genetics underlying behavioral problems, primarily in children. As a part of this interest he founded and currently directs the BCH Fragile X Program. He is currently developing a detailed phenotyping registry with a view toward integrating this with translational genetic research endeavors. In addition, from a basic science perspective, he has been working with Joseph Coyle at McLean Hospital investigating epigenetic developmental risk factors for schizophrenia.

### 113.1 INTRODUCTION

Etiologically, addictions are multistep pathologies that, by definition, require exposure to an agent, which is often a psychoactive substance. The probability of initial use as well as the probability of progression toward a pathological pattern of use (substance use disorder) is influenced by characteristics specific to the individual (e.g. genotype, sex, age, cohort and psychopathology), environment (e.g. drug availability, social support, stress and socioeconomic status) and addictive agent (e.g. addictive liability, mode of use or administration, physiological response and secondary pathology). Genetic and other influences may differ for each transitional step in the pathway to addiction.

Once use is initiated, repetitive exposure to the agent, and cycles of intoxication and withdrawal, induce neuroadaptive changes that further promote drug-seeking behaviors and ultimately lead to the maladaptive, persistent, and uncontrolled patterns of use that characterize addictions. These neuroadaptive changes are the bases for the establishment of tolerance, craving, withdrawal, and persistent affective disturbances that appear after consumption ceases (1). Together with failure to address and manage preexisting vulnerability factors, the self-maintaining and progressive neurobiology of addictions makes these disorders chronic and relapsing in nature. The wide variety of addictive agents includes foods, sex, video gaming and gambling. Any of these agents may lead to an “addicted state” through neurobiological pathways partially overlapping with those involved in addiction to psychoactive substances (2). As will be discussed, addictive agents vary substantially in addictive liability and there may be a relationship between this

critical property of addictive agents and the inheritance of liability to addictive diseases.

#### 113.1.1 Epidemiology

Worldwide, drug use is both widespread and common. According to the World Health Organization (WHO), there are 2 billion people who consume alcoholic beverages and 76.3 million with diagnosable alcohol use disorders, 1.3 billion tobacco users, and 185 million users of illicit drugs ([http://www.who.int/substance\\_abuse/facts/global\\_burden/en/](http://www.who.int/substance_abuse/facts/global_burden/en/)). In the United States, according to the 2009 National Survey on Drug Use and Health (NSDUH), 130.6 million people aged ≥12 years (51.9% of the American population within this age range) are current drinkers. According to the same survey, approximately 21.8 million people older than 12 years (8.7% of the population) had in the last month used an illicit drug including marijuana/hashish, cocaine, heroin, hallucinogens, inhalants, or prescription-type psychotherapeutics used without a medical prescription. Prevalence of current illicit drug use among youth aged 12–17 years has declined from 11.6% in 2002 to 9.3% in 2008, although rates trended higher in 2009 (10.0%). Similar trends have been observed for young adults (age 18–25 years). Changes in use of illicit drugs are mainly driven by consumption of marijuana, the most commonly used illicit drug. The worldwide large-scale consumption of nicotine with accompanying epidemics of smoking-related cancers and cardiovascular diseases is a twentieth century phenomenon initiated by the packaging of bright-leaf tobacco into the cigarette (3). Warning requirements, advertising and sales restrictions, and public education

efforts have had a positive effect. According to the Monitoring the Future Survey (MFS), nicotine use in American youth began to decrease in 1997, and continues to do so (4).

Most people are able to use addictive agents in moderation and only a minority develop pathological patterns of use (5). However, the contribution of psychoactive substances to the global burden of illness, disability, and death is high, and from a public health perspective this disease burden is directly related to use. In the United States, the Prohibition era, which began at midnight on 16 January 1920, as a result of the 18th Amendment and was proceeded by a vigorous Temperance Movement, was marked by a dramatic reduction in alcohol use and in cirrhosis deaths (which declined to about half former rates). Following the end of Prohibition in 1933 as a result of the 21st Amendment, and a process of gradual repeal of state-wide prohibitions that lasted until 1966, there was a 56% increase in per capita alcohol consumption, with an accompanying return of cirrhosis deaths to their former level. During the 1950s, there were slight changes in alcohol intake. The 1960s and 1970s saw large increases. Since 1980 there has been an overall steady decline.

Most nicotine and approximately half of alcohol are consumed by individuals who have a specific addiction diagnosis. Nicotine-dependent and psychiatrically ill individuals consume about 70% of all cigarettes smoked in the United States (6). Alcohol-dependent individuals are responsible for about 50% of the social, legal, and interpersonal alcohol-related problems in society (7).

Gambling is an example of a nonpharmacologic addictive agent. Pathological gambling is currently classified as an impulse control disorder rather than an addiction. However, monetary rewards in gambling tasks activate the brain in a similar fashion as addictive drugs (8) with hypersensitivity to these rewards in problem gamblers (9). Gambling is common, and has become increasingly so in the past several decades with new access to government sponsored lotteries in most states and some form of legalized gambling in almost all, and general access to casinos, slot machines, and Internet gambling. Some 80% of Americans have gambled, and many become pathological gamblers. Estimated rates of problem gambling, which combines problem and pathological gambling, range as high as several percentage. However, the National Comorbidity Survey, which used the Composite International Diagnostic Interview (CIDI) and DSM-IV criteria, estimated that the rate of pathological gambling was 0.6% in an epidemiologically ascertained sample of 9282 individuals (10). The British Gambling Prevalence Survey (<http://www.gamblingcommission.gov.uk>) has tracked the prevalence of gambling and problem gambling in the United Kingdom, where the prevalence of problem gambling is also 0.6%.

A variable used to estimate impact of diseases on public health is Disability Adjusted Life Years (DALYs), which is years of life lost because of premature mortality or disability. Worldwide, alcohol subtracts 69.4 million DALYs, which represents 4.5% of all DALYs ([http://www.who.int/substance\\_abuse/facts/alcohol/en/index.html](http://www.who.int/substance_abuse/facts/alcohol/en/index.html)); tobacco 59.1 million (4.1%); and illicit drugs 12.2 million, representing 0.8% ([http://www.who.int/substance\\_abuse/facts/global\\_burden/en/](http://www.who.int/substance_abuse/facts/global_burden/en/)). The addiction disease burden is also unequally distributed across countries, gender, and age groups. Psychoactive substances have a higher social impact in the United States and Europe than in developing countries, where life expectancies are shorter and most common causes of premature death are infectious diseases rather than addictions. Drug use is more common in men than in women. However, male-to-female ratios for use of psychoactive substances have narrowed, consistent with the changing social roles of women. The use of alcohol and other drugs by teenage girls is now similar to rates of consumption by boys in both the United States and Australia (11,12).

Illicit drug use inflicts its largest effects on mortality in adolescence and young adulthood, alcohol mainly before age 60, and 70% of tobacco-related deaths occur after the age of 60 ([http://www.who.int/substance\\_abuse/facts/global\\_burden/en/](http://www.who.int/substance_abuse/facts/global_burden/en/)). From an economic perspective, the cost of addiction in the United States is approximately \$484 billion/year (\$138 for smoking, \$161 for illicit drugs, and \$185 for alcohol). The societal cost of addiction is comparable to the worst chronic diseases, including diabetes (\$131.7 billion/year) and cancer (\$171.6 billion/year) ([www.drugabuse.gov/about/welcome/aboutdrugabuse/magnitude](http://www.drugabuse.gov/about/welcome/aboutdrugabuse/magnitude)).

The majority of users of addictive agents do not progress to dependence and the conditional prevalence of dependence among users is different for various agents. According to the National Comorbidity Survey (NCS) (5) the highest risk of dependence among users is for nicotine, 31.9%, double that of cocaine. Risk factors for the development of substance use disorders include preexisting psychopathology (especially a preexisting substance use disorder) and family history of a substance use disorder (13,14). Age at first use is a powerful predictor. Odds of lifetime substance dependence among users are reduced by 4% for illicit drugs and 9% for alcohol for each additional year drug use onset is delayed (15,16). Studies on offspring of addicted patients also reveal that different risk factors may be involved at different stages of the development of addiction. Peer influences are most important for exposure and initial pattern of use, whereas familiarity and psychopathology play a more salient role in the transition to problematic use (14). Addiction occurs more often within a matrix of social and economic disadvantage. The poor and the deprived have higher rates of mental disorders in general, including substance use disorders (WHO, 2002; available at <http://www.who.int/whr/2001/chapter1/en/>

[index2.html](#)). Substance use/misuse is strongly related to determinants of overall level of population health including education, social support network, income, social status, and living conditions including housing, nutrition, water and environmental quality, employment, and access to health services. Addictions partially mediate the impact of these determinants on health. The relationship between mental illness and poverty is complex, reciprocal, and self-sustaining.

### 113.1.2 Definitions of Disease

There are currently two widely used systems for diagnosing substance use disorders: the Diagnostic and Statistical Manual of Mental Disorder (DSM) of the American Psychiatric Association (APA) and the International Classification of Disease (ICD) of the World Health Organization (WHO).

Both systems recognize two types of substance use disorders: substance dependence and substance abuse (DSM)/harmful use (ICD). DSM-IV criteria for dependence (Table 113-1) are similar to ICD-10 criteria (Table 113-2), whereas DSM-IV Abuse and ICD Harmful Use differ somewhat (17). The ICD-10 differs in excluding Harmful Use among patients with current Dependence, but not in patients who have ever had Dependence.

The development of valid and reliable criteria for addictive disorders represented a fundamental contribution to communication between physicians as well as for research. DSM and ICD criteria provide a unifying framework for epidemiology, treatment, and genetic research worldwide (17). However, current nosology

of addiction has important limits for treatment and research. The diagnostic categories are syndromic (based on clusters of symptoms and clinical course) and not etiologically based (18). The diagnoses are categorical, assuming a cutoff between normal and abnormal variation, when in fact many of the problems associated with addiction are found in people who fall below the threshold for diagnosis (7). Pathological forms of use may be underdiagnosed using the categorical DSM approach. Binge drinking is a pattern of alcohol use characterized by intense bouts of episodic drinking (binge) during which a large quantity of alcohol is consumed. Between these episodes, the binge drinker may refrain from drinking. In some American Indian Tribes, binge drinking is a common pattern of alcohol use that is generally, but not always, present in the context of alcohol dependence but that is itself a strong independent predictor of problems in all four DSM addiction major symptom areas: social, work, physical, and violence/lawlessness (19). Furthermore, there is a need to understand, and integrate, etiologic factors that act across diagnostic boundaries. Twin studies detect evidence of etiological factors shared between addictions and other psychiatric diseases (20) and linking normal (personality) and abnormal variations (psychopathology) (21,22). Thus, addiction disease categories are etiologically connected to other psychiatric diseases and to “normality.” Future versions of the DSM may incorporate dimensional indices such as age at onset, years of drug use, frequency of use, and quantity of use. However, it is improbable that the nosology of addiction will advance until neurobiological indicators, including genotypes, are integrated.

**TABLE 113-1 Diagnostic Criteria for Substance Dependence and Abuse According to the DSM-IV-TR**

Criteria for substance dependence, according to DSM-IV-TR

≥3 of the following occurring at any time in the same 12-month period

A maladaptive pattern of substance use, leading to clinically significant impairment or distress

(1) Tolerance, defined by either

- (a) A need for markedly increased amounts of the substance to achieve intoxication or desired effect
- (b) Diminished effect with continued use of the same amount of substance

(2) Withdrawal, defined by either

- (a) The characteristic withdrawal syndrome for the substance
- (b) The same (or similar) substance is taken to relieve or avoid withdrawal symptoms

(3) The substance is often taken in larger amounts or over a longer period than was intended

(4) There is a persistent desire or unsuccessful efforts to cut down or control substance use

(5) A great deal of time is spent in activities necessary to obtain the substance, use the substance or recover from its effects

(6) Important social, occupational or recreational activities are given up or reduced because of substance use

(7) The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance

Criteria for substance abuse, according to DSM-IV-TR

≥1 of the following occurring at any time in the same 12-month period

(1) A maladaptive pattern of substance use, leading to clinically significant impairment or distress

- (a) Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home
- (b) Recurrent substance use in situations in which it is physically hazardous
- (c) Continued substance use despite having social or interpersonal problems caused or exacerbated by the effect of the substance
- (d) Recurrent substance-related legal problems

(2) The symptoms have never met the criteria for substance dependence for this class of substance

**TABLE 113-2 Diagnostic Criteria for Substance Dependence and Harmful Use According to the ICD-10**

Criteria for substance dependence, according to ICD-10

≥3 of the following present together at some time during the previous year

- (1) A strong desire or sense of compulsion to take the substance;
- (2) Difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use;
- (3) A physiological withdrawal state when substance use has ceased or been reduced, as evidenced by the characteristic withdrawal syndrome for the substance or use of the same (or a closely related) substance with the intention of relieving or avoiding withdrawal symptoms;
- (4) Evidence of tolerance, such that increased doses of the psychoactive substances are required in order to achieve effects originally produced by lower doses
- (5) Progressive neglect of alternative pleasures or interests because of psychoactive substance use, increased amount of time necessary to obtain or take the substance or to recover from its effects;
- (6) Persisting with substance use despite clear evidence of overtly harmful consequences, such as harm to the liver through excessive drinking, depressive mood states consequent to periods of heavy substance use, or drug-related impairment of cognitive functioning; efforts should be made to determine that the user was actually, or could be expected to be, aware of the nature and extent of the harm.

Criteria for harmful use, according to ICD-10

The diagnosis requires that actual damage should have been caused to the mental or physical health of the user.

Harmful patterns of use are often criticized by others and frequently associated with adverse social consequences of various kinds.

The fact that a pattern of use or a particular substance is disapproved of by another person or by the culture, or may have led to socially negative consequences such as arrest or marital arguments is not in itself evidence of harmful use.

Acute intoxication or "hangover" is not itself sufficient evidence of the damage to health required for coding harmful use.

Harmful use should not be diagnosed if dependence syndrome, a psychotic disorder, or another specific form of drug- or alcohol-related disorder is present.

### 113.1.3 Subtypes of Addiction

The general recognition of the heterogeneous and multifactorial nature of addiction has led to the classification of addicted patients into more clinical homogeneous subtypes in which etiologic factors, including genes, tend to be shared, and represents a first systematic effort to individualize treatment and prevention. Characteristics used to subclassify alcoholism include age at onset (23), personality, comorbidity with other psychopathological conditions, familiarity and mode of inheritance, severity, clinical course, and response to treatment. Most of the typologies proposed recognize the existence of two basic types. Type A (e.g. Cloninger type I) comprises approximately two-thirds of alcoholics and is characterized by late onset, slower course, and better prognosis. Type B (e.g. Cloninger type II) is characterized by stronger familiarity, antisocial behavior, earlier onset, rapid course, and poorer prognosis. Type I alcoholism thus falls more in the category of internalizing disorders and type II in the externalizing disorder domain. The A/B distinction, first applied to alcoholism, appears to be applicable to other addictions (24). Typological systems identifying more than two categories also identify what appear to be similar categories, for example, negative-affect alcoholism, characterized by high-level depression (25,26). Physicians individualize therapy for addicted patients in many ways, for example, by addressing specific risk factors, barriers to abstinence, family and community supports, and medical consequences, but to this point formal diagnostic subclassification has mainly been a tool in research. Ondansetron was found to be more effective in early-onset alcoholics (27). Serotonin-specific reuptake inhibitors (SSRIs) seem to be effective in type A but not in type B alcoholics (28). Central serotonin dysfunction may

be specifically linked to type B alcoholism (29,30). Some genetic variants (e.g. the serotonin transporter (31) and the 5HT1B receptor (32)) have been shown to confer risk mainly in specific subgroups of alcoholics.

### 113.2 GENETIC ASPECTS OF ADDICTION

Evidence from family, adoption, and twin studies converge on the relevance of genetic factors in the development of addictions (13,33–38). The increased risk among relatives of addicted probands in the same family might result from either environmental or genetic influences. Twin studies and studies on adoptees can disentangle those contributions. In the classical twin study design the phenotypic resemblance of monozygotic (MZ) twins (who share 100% of their genes) is compared to that of dizygotic (DZ) twins (who share approximately 50% of their genes) to estimate three main sources of variation (Figure 113-1):

- (1) Heritability (A): Proportion of variance due to additive (A) genetic factors.
- (2) Shared (or common) environment (C): Proportion of the variance due to environmental factors shared by members of the same family. C can also be directly measured in the context of adoption.
- (3) Unique environment (E): Proportion of the variance due to environmental factors unique to the individual. This term also includes variance attributable to measurement error.

Both A and C are sometimes collectively called familial influences because they contribute to similarities between members of the same family.

It has already been noted that the diagnostic assessment of addictions is imperfect. The usual effect of

**FIGURE 113-1** Twin studies: heritability path diagram: the phenotypic resemblance of monozygotic (MZ) twins (who share 100% of their genes) is compared to that of dizygotic (DZ) twins (who share approximately 50% of their genes) to estimate three main sources of variation: 1. Heritability=proportion of variance due to additive (A) genetic factors; 2. Shared (or common) environment (C)=proportion of the variance due to environmental factors shared by members of the same family; 3. Unique environment (E): proportion of the variance due to environmental factors unique to the individual.

measurement error is to limit the maximum heritability (A) and to increase the proportion of variance attributable to E. In the same vein, it is important to stress that A, C and E are latent (unmeasured) influences that should not be interpreted as absolute values. They provide broad estimates of sources of variation in the particular context in which they are evaluated, and do not, positively or negatively, predict effects of intervention to prevent or treat addictions. Twin studies failed to take into account gene by environment interaction. Furthermore, they do not inform us of sources of variation at the individual level. Nor are they informative of the specific genes and environmental factors involved.

Several questions that can be addressed by twin studies of addictions include the following: Are addictions heritable? Do genetic and environmental risk factors contributing to drug initiation, the same contributing to drug addiction? What is the nature of inheritance? Are the genetic and environmental risk factors agent specific or nonspecific? Are genetic and environmental factors independent?

### 113.2.1 Heritability of Addiction

Weighted mean heritabilities for substance use disorders (substance dependence, substance abuse or dependence, or persistent use) computed from several studies of large, carefully phenotyped cohorts of twins are shown in Figure 113-2 (39). Addictions include several of the most heritable psychiatric diseases, as well as disorders that are not highly heritable. Heritability is lowest for hallucinogens (0.39) and highest for cocaine (0.72).

Heritability estimates are usually higher for dependence than abuse and for abuse than use; however, “no pathological drug use” and “initiation of use” are also heritable characteristics (35,37,40).

**FIGURE 113-2** Heritability (weighted means and ranges) of 10 addictive disorders: hallucinogens, cannabis, stimulants, sedatives, opiates, cocaine dependence or abuse, alcohol dependence, smoking, caffeine consumption or heavy use, and pathological gambling. Weighted heritability ( $h^2$ ) means were computed using data from large national surveys of adult twins. (Adapted from Goldman et al. (39).)

### 113.2.2 Addiction Liability and Heritability

Drugs and other agents differ in addiction liability (e.g. potential of an agent to lead to addiction). Although addiction liability is difficult to quantify, Goldstein and Kalant (41) ranked the relative risk of addiction of different psychoactive substances. Their rankings were based on animal behavioral models in which the addictiveness of a substance is measured by the pattern of self-administration of a drug (e.g. how many times an animal will press a lever to obtain the injection of a drug or the rapidity of reinstatement of high levels of consumption after a period of enforced abstinence). As shown in Figure 113-3, addiction liability is nominally correlated

with heritability. Cocaine and opiates, which are the drugs with the highest addictive properties, are also the most heritable. On the other hand, hallucinogens are among the least addictive, and least heritable. This positive correlation between addictive liability and heritability predicts that part of what is inherited is variation in the core neurobiology of addiction, potentially including

**FIGURE 113-3** Heritability ( $h^2$ ) versus approximate ranking for relative risk of addiction. Heritability estimates for addiction correlate linearly with the addictiveness of the agent. Relative risk of addiction is expressed on a five-point scale, one indicates the lowest risk and five denotes the highest risk. (Adapted from Goldman et al. (39).)

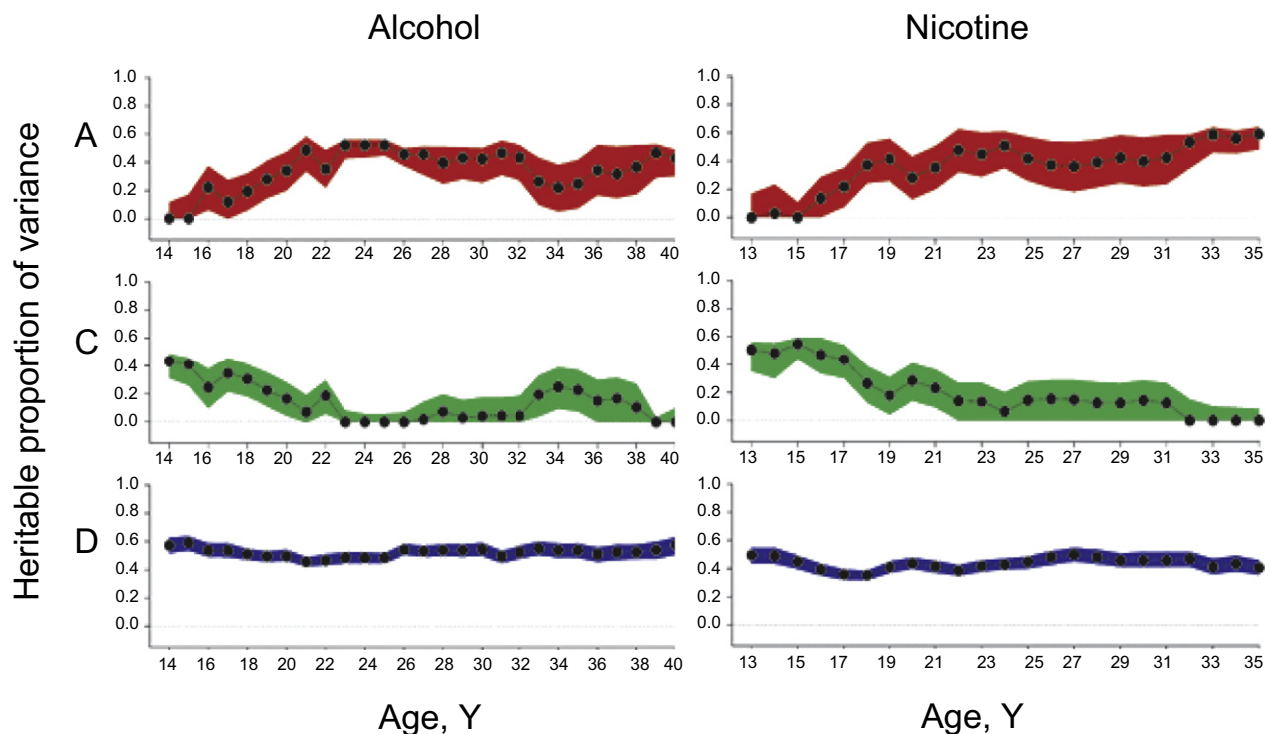

reward, behavioral control, obsessionality/compulsivity, and stress/anxiety response.

### 113.2.3 Developmental Dependence of Genetic and Environmental Risk

Genetic and environmental influences modulating risk of addiction, as well as other complex phenotypes, change during the lifespan. These developmental differences are thought to be both quantitative (i.e. the relative contribution of genetic and environment factors change over time) and qualitative (i.e. the specific genes and environmental factors involved in addiction during a certain developmental period are different from those involved in different periods). Longitudinal twin/family studies allow the exploration of developmental differences in gene/environment effects.

**113.2.3.1 Quantitative Differences.** Longitudinal studies reveal that the impact of genetic and environmental factors on addictions changes during development and across the lifespan. Kendler et al. (42) found that the effect of shared environment (C) declines moving from adolescence into adulthood and disappears by age 35 for nicotine and by age 40 for alcohol (Figure 113-4). In contrast, gene effects (A) are undetectable in early adolescence but their relative importance gradually grows.

A possible explanation for these results is that during the progression to adulthood, the individual has

**FIGURE 113-4** Age dependency of genetic and environmental contributions to variation in liability to alcohol (left) and nicotine (right) use. Additive genetic effects (A), familial environmental factors (C) and individual-specific environment (E) are represented by age in years (Y). The actual parameter estimates for A, C, and E are depicted by the black lines. Colored regions represent the possible range of estimates  $\pm 1$  standard error. For both nicotine and alcohol use, genetic influences increase and shared family environmental influences decrease, moving from adolescence to adulthood (see text). (Adapted with modification from Kendler et al. (42).)

increasing latitude to shape his/her own choices and social environment, thus increasing the relative role of genotype (43) (see also Section 113.2.6.1). Another possible explanation is that the action of some genetic factors appear only after repetitive exposure to the addictive agent (see also gene  $\times$  environment interaction), or by genes that act only after the brain has fully developed.

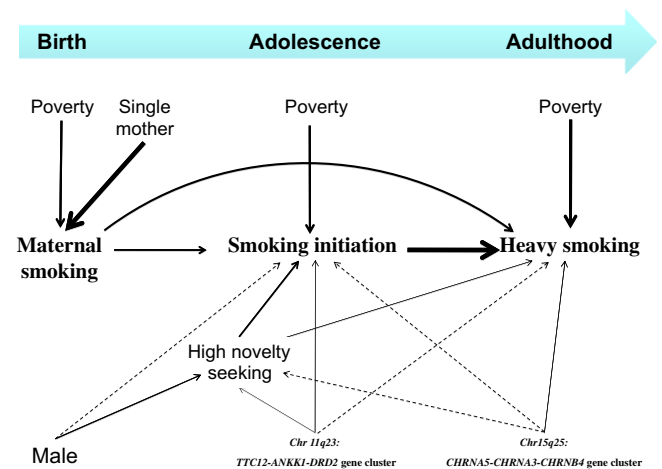

**113.2.3.2 Qualitative Differences.** Addiction is a multistep process from initial exposure to the agent, often occurring in adolescence, toward the development of maladaptive patterns of use and psychical/psychological dependence. In this view, it is not surprising that genes involved in initiation might be different from genes that are involved in persistence and dependence. Indeed, twin studies have shown that genetic risk factors for initiation only partially overlap with genetic determinants for developing substance use disorders. In a large twin study, genetic risk factors for initiation of illicit drug use were responsible for about half of heritability of abuse/dependence (40). This is consistent with the hypothesis that some genes influence addiction by increasing the probability of initiation (e.g. genes influencing temperament traits such as sensation/novelty seeking that promote drug experimentation) and other genes modify response to the drug and the probability of persistent use (e.g. genetic variants modulating the pharmacodynamics/pharmacokinetic of substance). For example, genetic variation within the chromosome 11q23 region where the gene encoding for the dopamine receptor 2 (DRD2) is located, has been associated with smoking initiation in adolescents and its effect on smoking appears to be partially mediated by its effect on high novelty seeking, a personality characteristic that is associated with drug-seeking behavior (22). Similarly, genetic variation within the monoamine oxidase A (MAOA) gene is associated with increased impulsive/antisocial behavior that usually predates alcohol and illicit substance use (44). In contrast, genetic variation within the *CHRNA5-CHRNA3-CHRNA4* gene cluster on chromosome 15q25 appears to be involved in the development of a heavy pattern of use in adulthood (22) and in smoking persistence (Figure 113-5). Among environmental risk factors, low socioeconomic status appears to increase risk of nicotine abuse across all life.

### 113.2.4 Shared and Unshared Inheritance of Different Addictive Disorders

Comorbidity (e.g. co-occurrence of different disorders in the same individual or an excess of disease co-occurrence in a population) between different addictive disorders is frequent (45–47). Studies on genetically informative samples (e.g. adoptive or twin studies) can measure the relative contribution of genes and environment to comorbidity by evaluating the cross-transmission of different traits. In this way, shared risk factors common to different

types of drugs or between addiction and other disorders can be differentiated from specific risk factors contributing to vulnerability for a particular addiction but not to the others. Based on results from these types of studies, inheritance of addiction vulnerability is in part substance specific but a large portion of vulnerability to addiction is attributable to shared factors that act across different addictive agents, including agents from seemingly different categories (48).

**113.2.4.1 Cross-Inheritance of Addictions.** Large twin studies reveal an overlap between genes for alcoholism and illicit drug use disorders (20,49). In a sample of male and female adolescents, a common vulnerability factor to alcohol, tobacco, and a combined class of illicit drugs had a heritability of 23% (50). Kendler et al. (51) explored the genetic overlap between several licit and illicit substances, including alcohol, caffeine, nicotine, cannabis, and cocaine, in a portion of a Virginia twin sample consisting of almost 5000 twins. In this study genetic risk factors for dependence on different psychoactive substances could not be explained by a single factor acting across all substances. Rather, two shared genetic factors were found: an illicit agent genetic factor mainly explained vulnerability to cannabis and cocaine dependence and a licit agent genetic factor mainly explained vulnerability to alcohol, caffeine, and nicotine. These

**FIGURE 113-5** Impact of genetic and psychosocial factors on smoking behavior moving from adolescence to midadulthood. Genes are the *TTC12-ANKK1-DRD2* gene cluster on chromosome 11q23 and the *CHRNA5-CHRNA3-CHRNA4* gene cluster on chromosome 15q25. Psychosocial risk factors include socioeconomic status, maternal smoking, and the personality characteristic of novelty seeking. The thicknesses of path lines are proportional to the strength of the association between the two variables connected by the path. Nonsignificant paths are shown with dashed lines. The effect of *TTC12-ANKK1-DRD2* gene cluster on smoking in adulthood is mainly indirect and mediated via its effect on smoking in adolescence and novelty seeking. In contrast, the effect of the *CHRNA5-CHRNA3-CHRNA4* gene cluster on smoking in adulthood is mainly direct and not mediated by smoking in adolescence or novelty seeking. Poverty and social disadvantage are associated with increased risk of smoking both in adolescence and midadulthood. (Adapted with modification from Ducci et al., (22).)

two factors were not independent but highly correlated. Large agent-specific genetic factors were found mainly for nicotine and caffeine (Figure 113-6).

**113.2.4.2 Cross-Inheritance of Addictions and Other Psychiatric Disorders.** Addictions frequently coexist with other psychiatric diseases, including both internalizing disorders (disorders marked by anxiety or problems of mood) and externalizing disorders (disorders marked by problems of impulse control) (46,47). Twin studies consistently reveal the existence of shared genetic influences between addiction and externalizing disorders (20,21,49). Longitudinal studies have shown that externalizing disorders of childhood such as conduct disorder (CD) and attention deficit hyperactivity disorder (ADHD) are important risk factors for the subsequent development of alcoholism (52). Evidence from twin studies for shared genetic influences between alcoholism and internalizing disorders is more controversial (53,54). However, longitudinal studies have shown that anxiety disorders such as panic disorder and social phobia predict subsequent alcohol problems in adolescents and young adults (55).

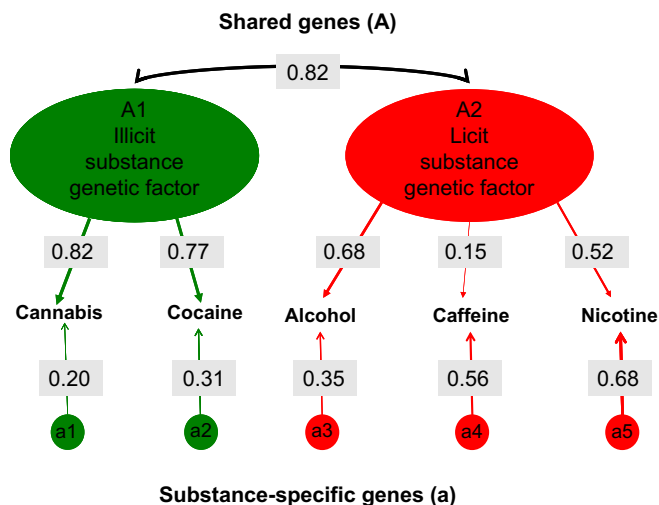

Overall, twin studies predict that genes involved in vulnerability to addiction include both agent-specific genes and genes that act on common pathways

involved in addiction to different agents. Agent-specific genes include genes involved in pharmacokinetic or pharmacodynamic processes specific to a particular drug. For example, genetic variation in alcohol metabolizing genes moderate risk to develop alcoholism. On the other hand, variation within genes involved in the pharmacodynamics of nicotine dependence moderate risk for nicotine addictions but not other types of addictions. Nonspecific genes include genes affecting neurobiological networks involved in vulnerability to different types of addictions as well as genes predisposing to addictions and other psychiatric diseases such as genes involved in reward, stress resiliency, behavioral control, and personality. For example, the dopamine system is fundamental for the reward effects of all addictive agents (56), and genetic variations in the gene encoding the dopamine two receptor (*DRD2*) have been linked to different types of addictions, although with some inconsistencies (57). As will be discussed, other genes such as monoamine oxidase A (*MAOA*), the serotonin transporter (*SLC6A4*), and catechol-O-methyltransferase (*COMT*) have been implicated in the shared genetic liability between addictions and other psychiatric diseases.

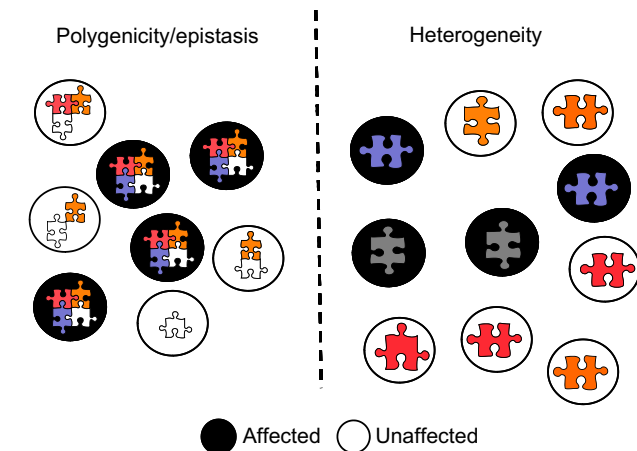

### 113.2.5 Mode of Inheritance

Genes influence addiction liability through a matrix of neural systems, molecular networks, and environmental interactions, providing a challenge for reductionism. Family studies do not reveal a simple Mendelian model of inheritance for any addiction. The genetic complexity of addictions can be expressed in a variety of ways: incomplete penetrance, variable expressivity, gene–environment interactions, and genetic heterogeneity. Two other sources of genetic complexity are polygenicity (the action of multiple variant alleles) and epistasis (nonadditive effects of combinations of genes), and for addictions these are strongly inter-related mechanisms because of the threshold nature of the trait. Vulnerability to addiction may be a continuous trait, but addictions are clinically defined as threshold traits, which is to some extent justified by the changes in brain functions that occur in addicted individuals.

**113.2.5.1 Polygenicity vs Genetic Heterogeneity.** Frequently it is posited that psychiatric diseases are likely to be polygenic because the function of the brain depends on the action of thousands of interacting genes, many of which have functional variants. As just mentioned, for a threshold trait such as addictions a requirement for the action of multiple variants would also lead to epistasis. However, the molecular complexity of the brain and multiple processes underlying addiction are likely to lead to genetic heterogeneity. As shown in Figure 113-7 (39), under the polygenic/epistatic model the presence of combinations of genetic variants (each shown in Figure 113-7 as a piece in a small puzzle) is required to express a certain phenotype.

**FIGURE 113-6** Shared and substance-specific additive genetic influences acting on symptom counts for cannabis, cocaine, alcohol, caffeine, and nicotine abuse or dependence. Two common genetic factors are identified, one for illicit substances (A1) and one for licit substances (A2). Substance-specific genetic influences (a1–a5) are represented at the bottom of the figure. Path values are standardized loadings and thus need to be squared to reflect the proportion of variation in liability in the observed variable accounted for by the factor. For example, the illicit substance genetic factor (A1) accounts for 0.67 ( $0.82^2$ ) of the total variance in cannabis symptoms in this population. The cannabis-specific genetic factor (a1) accounts for 0.04 ( $0.20^2$ ) of the variance in this trait. Therefore, the total variance of cannabis symptoms determined by genetic factors—heritability—is 0.71 ( $0.67 + 0.04$ ). The remaining variance ( $1 - 0.71 = 0.29$ ) is explained by environmental influences that are not represented here. The double-headed arrow connecting the illicit and licit substance genetic factors represents the genetic correlation between these factors (see text). (Adapted with modification from Kendler et al. (51).)

**FIGURE 113-7** Genetic complexity in unrelated individuals: polygenicity vs heterogeneity. Each risk allele is represented as a puzzle piece of different color or shape. Black circles indicate affected individuals and empty circles denote unaffected individuals. (Adapted from Goldman et al. (39).)

**FIGURE 113-8** Genetic complexity and twin concordance. Each risk allele is represented as a puzzle piece of different color or shape. Members of twin pairs are represented by squares. Black squares indicate affected individuals and empty squares denote unaffected. (Adapted from Goldman et al. (39).)

Under the genetic heterogeneity model different genetic variants produce the same phenotype in different individuals, but a single genetic variant can suffice to confer risk in an individual. Twin studies represent an important tool to clarify the relative importance of polygenicity/epistasis and heterogeneity in the inheritance of a trait, because polygenicity and heterogeneity generally have different effects on MZ:DZ concordance ratios, as shown in Figure 113-8.

Since MZ twins share all alleles and DZ twins only on average half, a polygenic model predicts a high discrepancy between the MZ and DZ concordance rates (high MZ/DZ ratio). DZ twins are unlikely to inherit exactly the same alleles at multiple loci, but the odds are 1/2 that a co-twin will inherit an individual risk allele. Certain neuropsychiatric disorders have high MZ:DZ ratios. For example, the MZ:DZ ratio for autism appears to be as high as 50:1. The MZ:DZ twin concordance ratios for several drugs (Figure 113-9) converge to 2:1, consistent with alleles of individual effect and with the genetic heterogeneity model.

In other words, systems of multiple loci are more likely to confer risk for addiction additively (e.g. one or at most a few major alleles lead to risk independently from the others). Nonadditive genetic influences that result from interaction between genetic mechanisms at a single locus (e.g. recessive action of alleles) or at different loci (e.g. epistasis) might contribute to the inheritance of cocaine, which has the highest MZ/DZ ratio (3.7:1).

Gene  $\times$  gene interaction studies in the addictions are sparse. In alcoholism, the protective effects of missense variants in *ADH1B* (Arg48) and *ALDH2* (Lys487) are additive (58), although these might have been thought to be synergistic because of their action in consecutive steps of the alcohol metabolic pathway. In nicotine addiction, two variants previously associated with smoking also appeared to act additively (22). The genetic risk variants involved are in the *CHRNA5-CHRNA3-CHRNA4* nicotinic acetylcholine receptor subunit cluster and in the *TTC12-ANKK1-DRD2*

**FIGURE 113-9** MZ/DZ twin concordance ratios for 10 addictions. MZ/DZ ratios tend to converge on two, consistent with the heterogeneity model (see text). (Adapted from Goldman et al. (39).)

cluster, which includes *DRD2*, a dopamine receptor important in nicotine reward. Adolescent carriers of three to four risk alleles (20% of the population) at these two loci had a 3-fold increase in odds of smoking regularly and 2.5-fold increase in odds of smoking occasionally as compared to noncarriers, who constitute 9% of the population. Carriers of one to two risk alleles were at intermediate risk. A similar stepwise increase in risk with allele dosage was observed in adulthood, and again consistent with additivity (Figure 113-10).

The mode of inheritance of a disease has implications for the manner in which genetic predictors may eventually be used in clinical treatment and in genetic counseling. Indeed, as more genetic risk variants for addiction (as well as other complex diseases) are discovered and extensive personalized genotyping and sequencing become widespread, there will be increased efforts to use multilocus genetic risk scores to predict specific diseases (59).

### 113.2.6 Interplay between Genetic and Environmental Factors

The simplest, and oldest, model for the etiology of behavioral differences and psychiatric diseases regarded genetic and environmental factors as separate and independent entities. This model polarized discussion, leading to the gene (*nature*) vs environment (*nurture*) debate, a false dichotomy.

The inheritance of addictions was a concern of the eugenics movement, which in the United States was led by Charles Davenport at the Cold Spring Harbor Laboratory. Social Darwinism led to the classification of people who were psychiatrically ill, cognitively deficient (for example, illiterate), or poor as genetically defective. In the first half of the twentieth century these ideas were promulgated in genetics textbooks. For example, the Kallikak family was used to illustrate the effects of

“bad breeding.” The founding father in the pedigree was a Revolutionary War soldier who sired offspring both by a dissolute barmaid and a Puritan wife. The barmaid’s side of the family tree had drunkards and criminals, with toadstools growing at the dark and twisted roots. The other branch of the family tree was supposedly replete with fine and moral citizens. Consequences of eugenics included the compulsory sterilization of many thousands of vulnerable individuals. *Buck vs Bell* was heard before the United States Supreme Court in 1927, Carrie Buck being a ward of the Virginia State Colony for Epileptics and Feeble-minded. Although Buck later became an avid reader, she had been proposed for sterilization because she was “feeble minded” and incorrigibly promiscuous (having given birth to a child after being raped). The clinching piece of evidence was that her mother had been a prostitute. Writing for the 8-1 majority, Chief Justice Oliver Wendell Holmes, Jr. stated,

*It is better for all the world, if instead of waiting to execute degenerate offspring for crime, or to let them starve for their imbecility, society can prevent those who are manifestly unfit from continuing their kind. The principle that sustains compulsory vaccination is broad enough to cover cutting the Fallopian tubes.*

Holmes then memorably concluded: “Three generations of imbeciles are enough.” Some 65,000 individuals were compulsorily sterilized in the United States, and there were similar programs in other countries, including Japan, Canada, and Sweden, where in that one nation 21,000 people were forcibly sterilized. The Eugenics era reached its nadir in Nazi Germany where >400,000 people were sterilized and >6 million institutionalized individuals, homosexuals, gypsies, and Jews were murdered on the false premise of their genetic inferiority.

**FIGURE 113-10** Additive effects of the *TTC12-ANKK1-DRD2* and *CHRNA5-CHRNA3-CHRNA4* gene clusters on smoking behavior in adolescence and adulthood. Risk of smoking heavily increases linearly with the number of risk alleles at the two loci. Odds ratios (OR) and 95% confidence intervals (CI). (Adapted from Ducci et al. (22).)

Although it is important to be aware that modern genetic studies on addictions and other psychiatric diseases have emerged from a desire to understand behavior and to prevent and treat these diseases, it remains imperative to be alert to misuse of genetic information.

Another ideologically tinged view of addictions and other psychiatric diseases is that these emerge only through upbringing, experience, and choice. In addition, in a confusion that we may charitably say is created by the difficulty of defining exact boundaries between what is and is not disease and because addictions involve choice and environmental exposure, it is sometimes alleged that these conditions are not diseases. However, addictions display the classic features of disease process, and are prevented and treated in the same fashion as other complex diseases, most of which also have volitional and environmental exposure components. The environmentalist viewpoint was also to some extent co-opted for political purposes, for example, by people who believe in equality of outcome rather than equality of opportunity. Regardless of whether their origins are genetic or environmental, behaviors can be used to stigmatize. American Indians have suffered from the “fire-water myth,” although particular American Indian communities have low rates of alcoholism and within tribes there is differential vulnerability owing to genetic variation. The Irish are frequently characterized as alcoholic, although rates of alcoholism are not higher than several other European countries. Differential vulnerability to alcoholism is again genetically transmitted within the Irish. Modern neuroscience has revealed that the potential for addiction is probably latent in all people, but to different extents. Destigmatization should flow from improved prevention and treatment and from a more sophisticated understanding of the role of natural processes in addiction, and the ways that these can be co-opted to lead to disease, and

because of the complexity of vulnerability such that all of us probably carry vulnerability alleles for one disease or another.

Genotype appears to determine reaction range—the range of possible responses to environment, and more importantly the probability of different reactions. Because people share the neurocircuitry of reward, it is likely that most or all are at some risk for addiction and could become addicted under certain circumstances. However, shifts in the level and type of environmental exposure can unveil new parts of the overall risk density distribution, as shown in Figure 113-11.

An important environmental risk factor is drug availability. Tobacco consumption and tobacco-related diseases in the United States have decreased dramatically in the last 50 years because of changes in public policy beginning with the Surgeon General’s warning in 1960, restrictions on indoor smoking and advertising, increased taxes on tobacco products, warnings placed on packaging and in advertisements, counter-advertising, and well-publicized lawsuits. As a consequence, different birth cohorts in the United States have faced different levels and qualities of exposure to tobacco. A large meta-analysis including more than 60,000 individuals has explored how the genetic impact of a synonymous variant in the nicotinic acetylcholine receptor subunit alpha three gene (*CHRNA3*) on risk for smoking changes across birth cohorts in the United States (Hartz et al., unpublished data). This variant is highly correlated with a functional missense polymorphism Asp398Asn located within the *CHRNA5* (see Section 113.2.6.1) and is therefore a proxy for Asp398Asn among Caucasians. The increasing social restriction may have strengthened the impact of this locus on smoking. The odds ratio (OR) effect of this locus was 1.6 for the 1970 birth cohort as compared to 1.18 for the 1950 birth cohort, who passed through adolescence

**FIGURE 113-11** Genotype-specific liability and disease threshold. Liability or predisposition to a disease is simplified here as a single continuous dimension. Once liability passes a threshold the discrete phenotype emerges (affected versus unaffected). Given a disease-linked locus with two different alleles (D and d), carriers of the three different genotypes (DD, Dd, dd) have three different liability curves that together compose the overall liability distribution for that population (assuming that this is the only disease-linked locus in this population). Factors that change the threshold will therefore change the number of affected and unaffected individuals within each genotype group as well as in the overall population.

and young adulthood when the cultural climate for smoking was more permissive. Such findings also suggest that social restrictions that are effective in reducing smoking behavior at the population level may be less effective for people with a stronger genetic propensity such as carriers of the asparagine allele.

In addition to environmental influences that are specific to the addictive agent, such as drug price, availability and advertising campaigns, many nonspecific environmental influences powerfully moderate risk of addictions. These nonspecific environmental factors include exposure to maltreatment during childhood (44), low socioeconomic status (60), adverse life events, low social support, poor parenting, religiosity (61), peer influences (62), and parental monitoring.

Having identified gene effects and environmental effects it is important to identify the two main types of violations of gene–environment independence. These are gene by environment interaction (Figure 113-12B–D) and the less well-recognized gene by environment correlation (Figure 113-12A).

**113.2.6.1 Gene by Environment Correlation.** A shown in Figure 113-12A, gene  $\times$  environment correlation (rGE) occurs when genotype correlates ( $r$ ) with the probability of exposure to an environmental risk factor. There are three main types of rGE: active rGE, evocative rGE, and passive rGE.

Active rGE occurs when an individual's genotype shapes her choice of environment. For example, children with CD, a precursor to antisocial personality disorder (APD), tend to seek out antisocial peers. Exposure to antisocial peers increases risk of developing antisocial behavior and addiction. An example of active rGE is the effect of *CHRNA5* Asn398 to increase risk of lung cancer. As already discussed, this functional allele is associated with heavy smoking. It thereby leads to the exposure of cells of the lung, and elsewhere in the body,

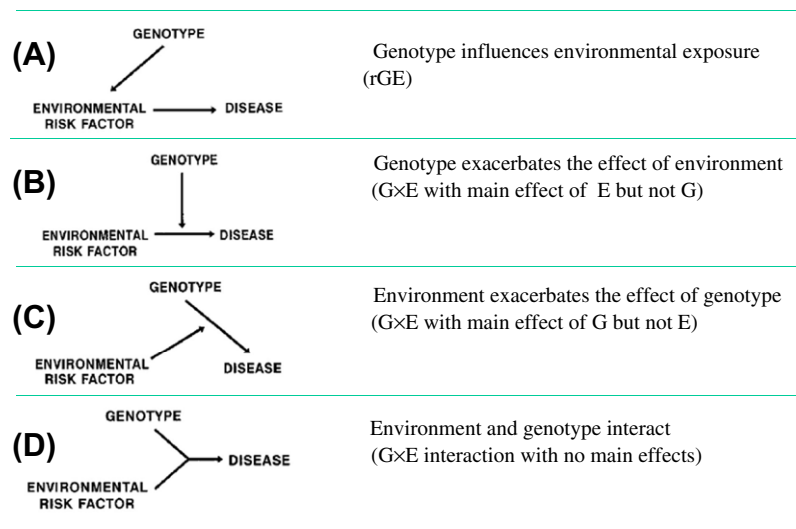

to carcinogens, and to cancer. A misinterpretation of these results would be that asparagine allele influences sensitivity to the carcinogenic effect of smoking; this is the  $G \times E$  model. The rGE model is of course consistent with a wealth of information on the carcinogenic effects of molecules in cigarette smoke.

In evocative rGE, an individual indirectly shapes his/her environment. For example, a child with CD may evoke harsher discipline from her parents, in turn promoting the risk of addictions and other pathologies.

In passive rGE, alleles conferring risk in a child also alter the behavior of the parent transmitting the allele. Thus, the children of an addicted parent are at enhanced risk both via transmission of risk alleles and via family environment and teratogenic effects of the drug. For example, maternal smoking is associated with increased risk of smoking in the offspring because mothers smoking heavily are at increased risk of carrying, and transmitting, the risk allele within the *CHRNA5* gene (63). In addition, mothers who smoke expose their offspring to a tobacco-enriched environment that is likely to promote smoking behavior.

Twin studies can address the existence of rGE by measuring the “genetics of the environment.” Although it may appear paradoxical, if behavior alters environmental exposures and if the relevant aspect of the behavior is subject to genetic influences, then the environmental factor will be heritable. Inheritance of environmental exposures has been observed. Kendler and Backer (64) reported modest to moderate heritabilities (ranging from 7 to 39%) for several categories of environmental factors important or potentially important in addiction vulnerability: stressful life events, parenting, family environment, social support, peer interactions, and marital quality.

An important example of rGE is age at first use of the psychoactive substance, which influences risk of becoming dependent. Early initiation of addiction use is associated with an increased risk of developing addiction. The

**FIGURE 113-12** Different patterns of gene (G)–environment (E) interplay: gene by environment correlation (A) and gene by environment interaction (B–D).

National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) revealed that odds of lifetime substance dependence among users were reduced by 4% for illicit drugs and 9% for alcohol for each additional year that onset of drug use was delayed (15,16). This association between age at initiation and risk can arise from different mechanisms. It can result from a direct causal effect (early onset directly increases risk) or might be mediated by genetic/familial influences (early onset and addiction result from a broad shared liability). Results from the Virginia Twin Registry study are more consistent with the second hypothesis. Prescott and Kendler (65) showed that co-twins with late onset of alcohol use had the same risk of becoming alcoholics as their sibling twins with early onset of alcohol use. This result indicates that the association between early exposure and alcoholism may result from a shared genetic liability and that early exposure does not independently influence risk of developing alcoholism. This is important, because prevention efforts at delaying drinking are likely to be useful for preventing alcohol-related accidents and injuries, but might not necessarily reduce risk of developing alcoholism in adulthood. The impact of early exposures to alcohol, and other addictive agents, remains a critically important issue: few would risk unnecessary early exposures in children with developing brains and imperfectly developed impulse control.

### 113.2.6.2 Gene by Environment Interaction.

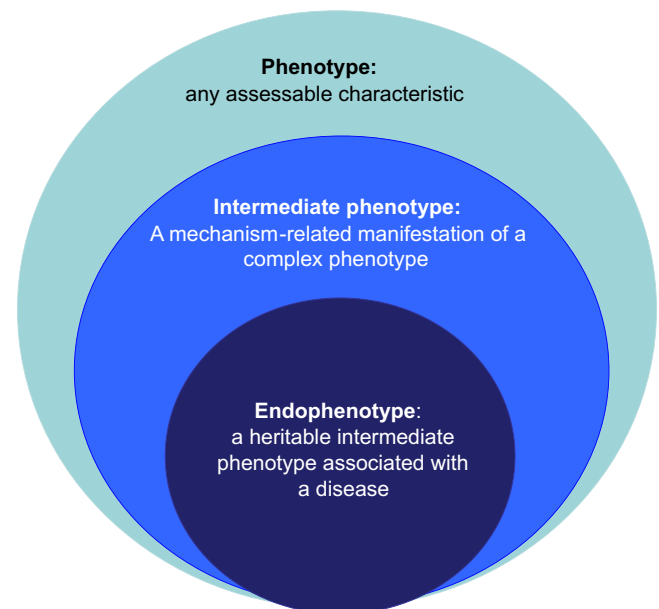

Gene  $\times$  environment interaction ( $G \times E$ ) occurs when the effect of the environmental exposure on a certain outcome is strongly influenced or contingent upon genotype and vice versa (gene effect on the outcome is contingent on exposure), see Figure 113-12B–D (for review see Reference (66)).

$G \times E$  has been observed for several functional alleles identified as having roles in addictions and other psychiatric disorders. By comparison with other complex diseases, including cancer, diabetes, cardiovascular disease, infectious diseases, and hematologic diseases, where genetic variation moderates resiliency and vulnerability to chemicals, pathogens, nutrients, caloric load, oxidants, and ionizing radiation, in psychiatric genetics much of the progress has been through discovery of alleles that influence stress resiliency. Severe childhood stress and neglect both increase vulnerability to addiction and multiple addiction-related psychiatric diseases, including APD, CD, anxiety disorders, and depression, with the risks of these common diseases being elevated several-fold in the stress exposed. However, not all people who are exposed to early life stress develop addiction or other psychiatric diseases, indicating wide variation in stress resiliency. Functional loci that have been shown to partially account for interindividual differences in stress resiliency include MAOA (44), the serotonin transporter (SLC6A4) (67), COMT (68), the corticotrophin-releasing hormone receptor 1 gene, neuropeptide Y (NPY) (69), and FKBP5 (70).

### 113.2.7 Progress through Intermediate Phenotypes

One strategy to discover gene effects in addictions and other etiologically complex diseases is the deconstruction of complex phenotypes into elements that are etiologically more homogeneous. Intermediate phenotypes access mediating mechanisms of genes and environmental effects on behavior. Heritable intermediate phenotypes that are disease associated have been termed “endophenotypes” (71) (Figure 113-13).

Several intermediate phenotypes have been specifically associated with addiction. These include alcohol-induced flushing, which is a protective endophenotype, and low response to the effects of alcohol, which is an endophenotype predictive of risk of alcoholism. In humans, the level of response to alcohol is believed to reflect mainly pharmacodynamic variation in response (72) rather than variation in metabolism. A low response to alcohol predicts increased risk of developing alcohol use disorders (73–75) and has been associated with genetic variation in the serotonin transporter gene (SLC6A4) and in the gene encoding the subunit  $\alpha 6$  of the gamma-aminobutyric acid receptor A (GABRA6) (76). Other intermediate phenotypes assist in the exploration of genetic vulnerability to addictions (as well as other psychiatric diseases), and these addictions-relevant intermediate phenotypes include electrophysiologic, neuropsychologic, neuroendocrinologic and, more recently, neuroimaging measures. Neuroimaging provides access to the neuronal mechanisms underlying emotion, reward, and craving and therefore represents an extraordinary tool to link genes to the neuronal pathways that produce behaviors (for review see (77)). For example, amygdala activation after exposure to

**FIGURE 113-13** Definitions of phenotype, intermediate phenotype, and endophenotype.

stressful stimuli predicts anxiety and captures interindividual differences in emotional response and stress resilience (78). On the other hand, activation of the prefrontal cortex during working memory performance is used to evaluate prefrontal cognitive function that is impaired in several psychiatric diseases including addictions.

As compared to complex phenotypes such as clinical diagnosis, intermediate phenotypes offer two main advantages:

- (1) They can help in identifying the neurobiological processes, or “missing links,” that translate gene effects into complex behavior.
- (2) They are less complex in their causal origins and therefore likely to be influenced by variations at fewer genes, thereby increasing the power to detect risk genetic variants (79,80). Indeed, effect sizes (i.e. the strength of the association) of genetic variations acting on intermediate phenotypes that are more proximal to gene action appear to be larger than effects on complex disease phenotypes such as clinically defined disease (79), and as illustrated, for example, by the dilution of action of a variant of NPY, an anxiolytic neuropeptide, from the molecular level (RNA and peptide level) to intermediate phenotypes (brain imaging) to anxiety (69).

### 113.3 GENE IDENTIFICATION

Two main strategies have been used and are increasingly integrated to identify genetic variations influencing addiction: (1) candidate gene and (2) genome-wide approaches. In the former, genes known to influence processes involved in the pathogenesis or treatment of addiction are selected. In the latter, the whole genome is interrogated simultaneously in a hypothesis-free way. A point of integration between the methods is the study of candidate genes located in chromosome regions implicated by genome-wide scans.

#### 113.3.1 Candidate Genes

**113.3.1.1 Alcohol Metabolizing Genes: *ADH1B* and *ALDH2*.** The alcohol dehydrogenase IB (*ADH1B*) and aldehyde dehydrogenase 2 (*ALDH2*) genes encode enzymes catalyzing consecutive steps in alcohol metabolism. In adults, these enzymes play an important role, although there are also several other enzymes that can carry out both these metabolic steps, including catalase, cytochrome P450, and additional enzymes in the *ADH* and *ALDH* gene families. In the liver, three *ADH* genes are expressed at high levels and to some extent at different times of development, and these three enzymes are primarily expressed in hepatocytes. *ALDH2* is encoded in the nuclear genome but the enzyme is translocated to the mitochondrion, where it plays a critical role in the ability of hepatocytes, and other cells throughout the body,

to metabolize acetaldehyde. The metabolic functions that have maintained these genes and this enzyme pathway through at least 80 million years of mammalian evolution are in fact somewhat obscure. A possible explanation is that the body has to utilize alcohols that are the product of bacterial fermentation in the gut. These enzymes also act on other important substrates including retinoids and neurotransmitters.

The product of *ADH* is acetaldehyde, a toxic intermediate that may react with a variety of biomolecules. Indeed, acetaldehyde adducts with DNA and both acetaldehyde and alcohol are formally recognized as mutagens. Acetaldehyde is a potent releaser of histamine, and can trigger the aversive flushing reaction. Symptoms include headache, nausea, palpitations, and flushing of the skin. Ordinarily, acetaldehyde is rapidly converted to acetate, and levels of acetaldehyde remain very low—in the nanomolar range. However, if aldehyde dehydrogenase is blocked by disulfiram (which is a medication used to help alcoholics maintain abstinence) or certain drugs used to treat protozoal infections (e.g. metronidazole) then the flushing reaction is observed after the ingestion of only small quantities of alcohol. If acetaldehyde accumulates the individual is at substantially increased risk of upper gastrointestinal (GI) cancer, and this can occur because of either pharmacologic blockade of aldehyde dehydrogenase or natural genetic variation, a factor that physicians may wish to consider in counseling individuals who drink despite carrying the genetic variations that will next be described (81).

Nature has provided two common natural examples of genetic predisposition to alcohol-induced flushing, and it is not surprising that the enzyme variants that lead to flushing are protective against the development of alcohol use disorder (Figures 113-14 and 113-15).

The most important functional loci at *ADH1B* and *ALDH2* are the *ADH1B* His48Arg missense polymorphism, in which Arg48 is a hyperactive allele acting in codominant fashion, and *ALDH2* Glu487Lys, in which the Lys487 allele inactivates *ALDH2* dominantly

**FIGURE 113-14** Functional polymorphisms in ethanol metabolism: *ADH1B* His48Arg and *ALDH2* Glu487Lys. Higher activity of *ADH1B*, conferred by Arg48, or lower activity of *ALDH2*, conferred by Lys487, leads to accumulation of acetaldehyde following alcohol consumption and the flushing reaction.

(a manifestation of the tetrameric structure of ALDH2). Higher activity of ADH1B, conferred by Arg48, or lower activity of ALDH2, conferred by Lys487, leads to accumulation of acetaldehyde following alcohol consumption and the flushing reaction. In east Asia populations (e.g. China and Japan), where both His48 and Lys487 are highly abundant, and in Jewish populations where His48 is abundant, many individuals carry genotypes protective against the development of alcoholism. The protective effect seems to vary across environments (82) and shows genotype–genotype additivity (58). Following up the connection of acetaldehyde to mutation,

both polymorphisms have also been associated with an enhanced risk of cancers of the oropharynx and esophagus (81) (Figures 113-16 and 113-17). As seen in the figure, rates of upper GI cancer tend to be higher in parts of the world where the ALDH2 Lys487 allele is abundant.

Both the ADH1B and ALDH2 polymorphisms appear to be ancient in human populations, occurring on characteristic and highly diverged haplotypes. On that basis it is unlikely that either the Arg48 or Lys487 were selected to high frequencies in east Asian populations as protective alleles against alcoholism. One possibility, still speculative, is that these polymorphisms alter susceptibility

### Structure leads to dominant action of Lys487

**FIGURE 113-15** ALDH2: A tetrameric oxidoreductase. ALDH2 is a tetrameric oxidoreductase, accounting for the dominant action of the Lys487 allele. His487/Lys487 heterozygotes have <5% of ALDH2 activity of His487/His487 homozygotes.

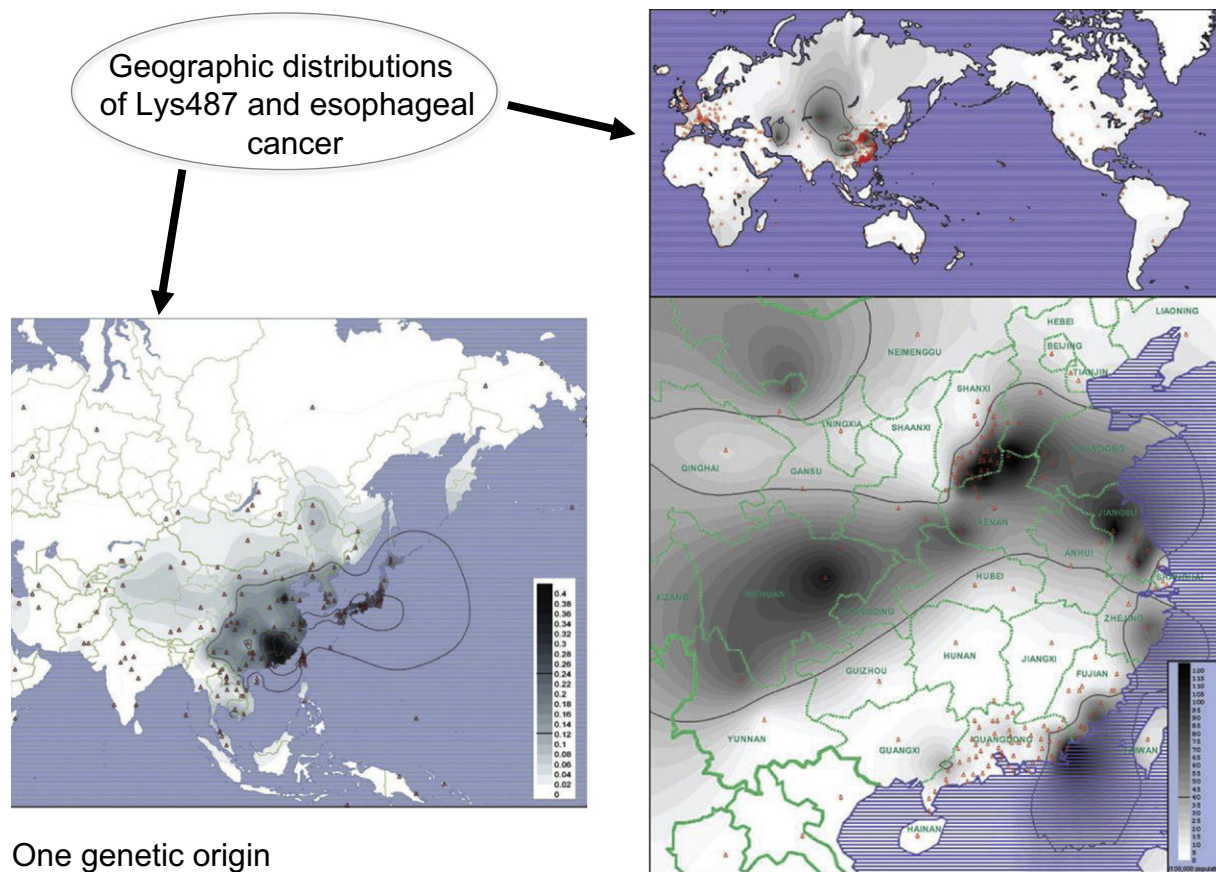

**FIGURE 113-16** Alcohol-induced flushing and cancer. The ADH1B His47Arg and ALDH2 Glu487Lys influence risk of developing cancers of the oropharynx and esophagus after alcohol consumption because of the toxic effect of acetaldehyde.

to protozoal infections of the gut, including amebiasis, because an action of metronidazole (an antiprotozoal drug of unknown mechanism) is to inhibit ALDH (83). However, regardless of the forces responsible for their high frequencies, the pervasive environmental exposure to alcohol that occurs in modern societies has added other dimensions to their effects.

**113.3.1.2 Genes Moderating Monoamines.** Monoamines including serotonin (5-HT), norepinephrine (NE), and dopamine (DA) are fundamental modulators of emotionality, cognition, reward, and behavioral response to stimuli. Therefore, it is unsurprising that genes regulating monoamines levels such as catechol-O-methyltransferase (COMT), MAOA, and the serotonin transporter (SLC6A4) have been implicated in vulnerability to several psychiatric diseases, including addiction, APD, depression and anxiety. In line with these ideas, drugs increasing monoamines in the synaptic cleft or drugs that target receptors of monoamine neurotransmitters are used in the treatment of several psychiatric diseases.

COMT metabolizes dopamine, NE, and other catecholamine neurotransmitters. COMT plays an important role in the regulation of dopamine in the prefrontal cortex because it is a region where dopamine transporter is less

expressed (84,85). COMT knockout mice have increased levels of dopamine in this brain region (86,87). In mammals, the COMT enzyme occurs in two forms: a soluble, cytoplasmic, protein (S-COMT) and a membrane-bound form (MB-COMT), which, in humans, has 50 additional amino acid residues at the N-terminus. S-COMT predominates in most tissues, accounting for 95% of total COMT activity (88). However, in the brain, the amount of MB-COMT activity is much higher (89). Val158Met is a common functional single nucleotide substitution of COMT (90), replacing methionine for valine at codon 158 of MB-COMT and at codon 108 of S-COMT. Via its effect on enzyme stability (91,92) the Met158 allele is three- to four-fold less active than Val158 (93), and the alleles act codominantly. Because of its higher activity and the importance of COMT for dopamine metabolism in the frontal cortex, the Val158 allele was predicted to lower dopamine level in that region. In line with this hypothesis, the Val158 allele has been associated with inefficient frontal lobe function evaluated with different psychological and neuroimaging methodologies (94–96). In addition, in a pharmacogenetic study, the COMT inhibitor tolcapone improved executive function in val/val homozygotes, but not in individuals homozygous for the met allele, a finding consistent with

**FIGURE 113-17** Geographic distributions of Lys487 and esophageal cancer (158). The Lys487 allele is highly abundant in southeast Asia, and the frequency falls off clinally. Lys487 is virtually absent in Europeans, Africans and Amerindian populations. Southeast Asia is also an epidemiologic hot spot for esophageal cancer, consistent with genetic epidemiological studies that have connected risk of esophageal cancer to moderate consumption of alcohol in carriers of the Lys487 allele. Acetaldehyde is a carcinogen (81).

the higher levels of cortical dopamine already expected in individuals with this genotype (97). On the other hand, the Met158 allele, although associated with better cognitive performance, is associated with decreased stress resilience and increased anxiety. This allele has been associated with increased anxiety among women populations (98), increased pain–stress response and a lower pain threshold (68,99), and increased amygdala reactivity to unpleasant stimuli (100). In certain addicted populations, e.g. polysubstance abusers (101), both the Val158 and Met158 alleles have been associated with addictions. The Val158 allele was found to be excess among methamphetamine, nicotine, and polysubstance addicts (101). On the other hand, in addicted populations with high frequencies of internalizing disorders, such as late-onset alcoholics in Finland (102) and Finnish social drinkers (103), increased risk appears to be conferred by the Met158 allele.

This story of multilevel association of a functional locus of the COMT underlines that a gene can influence different pathways to addictions, sometimes working in opposite directions. Frustratingly for researchers, substance use disorders are not etiologically defined and people become addicted for different reasons. An eventual use of genetic markers is to improve the nosology of these common diseases, but at present the disease diagnosis or some other relatively crude indicator (for example, the number of cigarettes or alcoholic drinks consumed each week) is often the primary phenotype being used in genetic analysis. From this perspective it is unsurprising that gene effects vary across different populations of patients (for example, addicted patients with different level of severity, different pattern of comorbidity, different age at onset, and different exposure to stress).

Addictions genetics is problematic if primarily conducted at the statistical level—it may be difficult to statistically replicate association to the crude addiction phenotype. Replication is an important scientific standard to establish validity, but it is not the only way to validate gene/phenotype relationships, and often does not further the goal of genetic studies, which is

to identify functional loci and mechanisms. The initial observation of genetic association, in which the statistical genetic study is treated as the first phase of a process, can lead to a more productive focus on intermediate phenotypes, clinical subgroups, individuals with particular histories of environmental exposure, and animal models. The goal is to connect gene to behavior through a rationally understood chain of causality, and as just described for COMT and the alcohol metabolic enzymes. In this regard, genes such as COMT and ALDH2 have validated roles in behavior, but the association findings to disease phenotypes, even now and years after discovery of these loci, do not measure up to the statistical standard required in the genome-wide association study (GWAS), which is approximately  $10^{-8}$ . However, as will be seen, that stringent standard also reflects the multiple testing that is performed as part and parcel of a GWAS.

The serotonin transporter (*SLC6A4*) is another gene that like COMT influences addiction and that is also not specific to a particular addictive agent, or to addiction. The serotonin transporter regulates the level of serotonin in the synapse, and this neurotransmitter has many functions in mood, behavior, appetite and impulse control. Reflecting these diverse actions, the most commonly prescribed category of medications for mental illness, namely, the SSRIs, is used to treat depression, anxiety, and chronic pain and their effect is mediated by blockade of the serotonin transporter. The serotonin transporter gene *SLC6A4* has a common variable-number tandem repeat (VNTR) in its promoter region (HTTLPR) (Figure 113-18).

The major alleles within this VNTR differ in the number of copies of a 20–23-bp imperfect repeated sequence. The L allele, which leads to increased transcription efficiency, has 16 copies of the repeat and the S allele has 14 copies (104). Furthermore, there is a relatively common, functional A>G single nucleotide polymorphism (SNP) within the L allele (105). The low-transcribing S allele has been inconsistently associated with trait anxiety, depression, and alcoholism. However, the effect of this allele on behavior appears stronger if stress exposure is taken into

**FIGURE 113-18** The serotonin-transporter-linked polymorphic region (HTTLPR). The human serotonin transporter gene has a common VNTR in its promoter region termed HTTLPR. The major alleles within this VNTR, namely, the L (long) and S (short) alleles, differ in the number of copies of a 20–23-bp imperfect repeated sequence. The L allele, which leads to increased transcription efficiency, has 16 copies of the repeat and the S allele has 14 copies. Furthermore, there is a relatively common, functional A>G SNP within the L allele (104, 105).

account. *HTTLPR* moderates the impact of stressful life events on risk of depression and suicide (106). Carriers of the low-transcribing *S* allele exhibit more depression and suicidality following stressful life events than *L* individuals with two copies of the allele (106).

Furthermore, *HTTLPR* has been shown to influence the activity of the amygdala, a brain region that regulates emotional response to environmental changes and is involved in the pathogenesis of depression and anxiety. Carriers of the low-activity allele display increased amygdala reactivity to fearful stimuli (67), reduced amygdala volume (107), and enhanced functional coupling between the amygdala and the ventromedial prefrontal cortex (108), a brain region that ordinarily represses amygdala activation. Closer to the molecular action of *HTTLPR*, an effect of the genotype on transporter expression in brain *in vivo* has been reported in post-mortem brain (109) and in life by neuroimaging (110), although not in all studies (111). The rhesus macaque has an orthologous polymorphism (*rs-5HTTLPR*) in the promoter region of its gene. Consistent with findings in humans, the macaque *rs-5HTTLPR* polymorphism influenced alcohol consumption and stress response, depending on rearing conditions. Carriers of the low-expression serotonin transporter genotype that were separated from their mothers at an early age (an animal model for childhood trauma) displayed higher stress reactivity and ethanol preference (112). The combined effect of *rh-HTTLPR* and environment on stress reactivity suggests that the influence of *HTTLPR* on behavior might be traced to altered regulation of the hypothalamic–pituitary–adrenal (HPA) axis.

Another key regulator of monoamine activity is MAOA that will be discussed in Section 113.3.3.

### 113.3.2 Genetic Mapping

Genetic mapping is the localization within the genome of genes underlying a disease on the basis of correlation with DNA variation, without the need for prior hypotheses as opposite to the candidate gene approach. For the addictions, genome-wide scans, including whole-genome linkage and whole-genome association (WGA), have implicated several chromosome regions.

**113.3.2.1 Whole Genome Linkage.** In whole-genome linkage a panel of polymorphisms is tested for meiotic linkage to a disease in family-based samples. This is done by identifying chromosome regions that are shared more often among phenotypically concordant relatives than among phenotypically discordant family members. The implicated chromosomal regions are usually very large, for example, greater than 10 Mb, and include therefore multiple genes. Therefore, a more refined search for the disease-associated gene within the disease-linked region is subsequently conducted via association or sequencing.

To perform whole-genome linkage analysis for alcoholism and other addictions, several large family-based

samples have been collected. These include the Collaborative Study on the Genetics of Alcoholism (COGA) (113); the Roscommon Study of Irish families (114); a sample of multiplex families from the Pittsburgh area (115); and samples collected from relatively isolated populations, including Native Americans (116,117) and Finns (32). Such isolated populations, and large families within them, are likely to confer the advantage of reduced genetic heterogeneity. A nonexhaustive list of convergent findings across family linkage studies includes a region on chromosome 4q that contains the alcohol dehydrogenase (*ADH*) gene cluster (113,114,116,117) and a chromosome 4p region containing a gamma-aminobutyric acid (*GABA*) receptor (*GABA<sub>A</sub>*) gene cluster (113,117). In the COGA sample there was also evidence for linkage to chromosomes 1 and 7, and to chromosome 2 at the location of an opioid receptor gene (115). A region on chromosome 1 was linked to alcoholism and depression in the COGA data set (118), further supporting the existence of a genetic overlap between alcoholism and internalizing disorders. A region on chromosome 7 was linked to alcoholism and/or illicit drug disorders in a subset of COGA families with high density for childhood and adult antisocial behaviors (119). Linkage analyses have also been conducted with intermediate phenotypes for alcoholism, including low response to alcohol (118), neurophysiological endophenotypes such as P300 (120), and reduced alpha power (121,122), implicating the corticotropin releasing factor-binding protein (*CRHBP*), another stress-related gene (122). Recently, multiple genome-wide significant loci for resting electroencephalography (EEG) were identified by GWAS (123), illustrating the power of combining GWAS with the endophenotype strategy. Chromosome regions identified by these studies overlap partially with those reported for alcoholism.

**113.3.2.1.1 *GABA<sub>A</sub>* Receptors.** Gamma-aminobutyric acid (*GABA*) is the primary inhibitory neurotransmitter in the central nervous system. *GABA<sub>A</sub>* receptor-mediated chloride currents into neurons are modulated by various drugs including ethanol, benzodiazepines, and barbiturates. *GABA* mediates many effects of alcohol including tolerance, dependence and cross-tolerance to benzodiazepines and barbiturates. A series of mouse ethanol-related behaviors, including preference, withdrawal severity, and sedation sensitivity, map to quantitative trait loci (QTL) regions where *GABA<sub>A</sub>* receptor gene clusters are located (124,125). In the rat, an Arg100Gln missense variant located in the *GABA<sub>A</sub>*  $\alpha 6$  subunit gene (*GABRA6*) was associated with variation in ethanol and benzodiazepine sensitivity (125). In humans, alcohol use disorder has been linked to both the chromosome 4 (121,126) and chromosome 5 *GABA* clusters. Linkage signals appear to derive from *GABRA6* on chromosome 5 (127) and *GABRA2* (121,126) and *GABRG1* on chromosome 4. In the COGA sample, the association between *GABRA2* and alcoholism was mainly driven by alcoholics who also abused illicit

substances, indicating that this gene might contribute to the shared liability to a different class of addictive disorders (128). A human variant of GABRA6 (Pro385Ser), which is located in the chromosome 5 cluster, was associated with sensitivity to alcohol (76) and benzodiazepines (129).

**113.3.2.2 Genome-Wide Association (GWAS).** Large-scale genotyping techniques have recently enabled genome-wide association analyses. These GWASs have the advantage of increased power for detecting effects of relatively common alleles (minor allele frequency (MAF) >5%) and more refined localization of signals to smaller chromosome regions as compared to family-based linkage analyses, which have a reciprocal advantage of being powerful for detecting effects of rare and uncommon alleles that are present in only a small proportion of probands and their families. An advantage of GWAS is that the same genotypes are obtained in different samples facilitating the combination of results from different studies in meta-analyses. This is a crucial aspect because extremely large study samples are necessary to be able to detect the small effects of many common variants on complex diseases. Of note in GWAS, up to 5 million SNPs can be simultaneously tested, raising the issue of false positive due to multiple testing. Therefore, genome-wide significance threshold is generally set at the  $p$  value level of  $10^{-8}$  rather than 0.05 or 0.01, which would be the equivalent  $p$  value for a single locus test.

GWASs have been particularly useful to identify genetic variation relevant to nicotine addiction. Results have been to some extent more disappointing for alcoholism; however, the datasets that have been analyzed have been substantially smaller.

**113.3.2.2.1 The *CHRNA5-CHRNA3-CHRNA4* Gene Cluster.** Although a large number of genetic loci potentially moderating smoking have been tested, only a few have been convincingly replicated. So far, the strongest evidence of association is for the *CHRNA5-CHRNA3-CHRNA4* gene cluster on chromosome 15q25 (130–135) (Figure 113-19). Gene clusters such as this one are thought to reflect ancient gene duplications, and can enable cis-regulatory effects on the expression of genes in the cluster.

Nicotinic acetylcholine receptors, nAChRs, are pentameric cholinergic receptors that form ligand-gated ion channels. They are key mediators of the effect of nicotine on the central nervous system. Neuronal subtypes of nAChRs include various homomeric or heteromeric combinations of 12 different nicotinic receptor subunits:  $\alpha 2$  through  $\alpha 10$  and  $\beta 2$  through  $\beta 4$ . The *CHRNA5-CHRNA3-CHRNA4* gene cluster encodes for the alpha five, alpha three, and beta four subunits. Association of genetic variation within this region to smoking behavior was initially discovered using a candidate gene approach (131,132) but was subsequently replicated by GWASs. GWASs detect a highly significant peak on chromosome

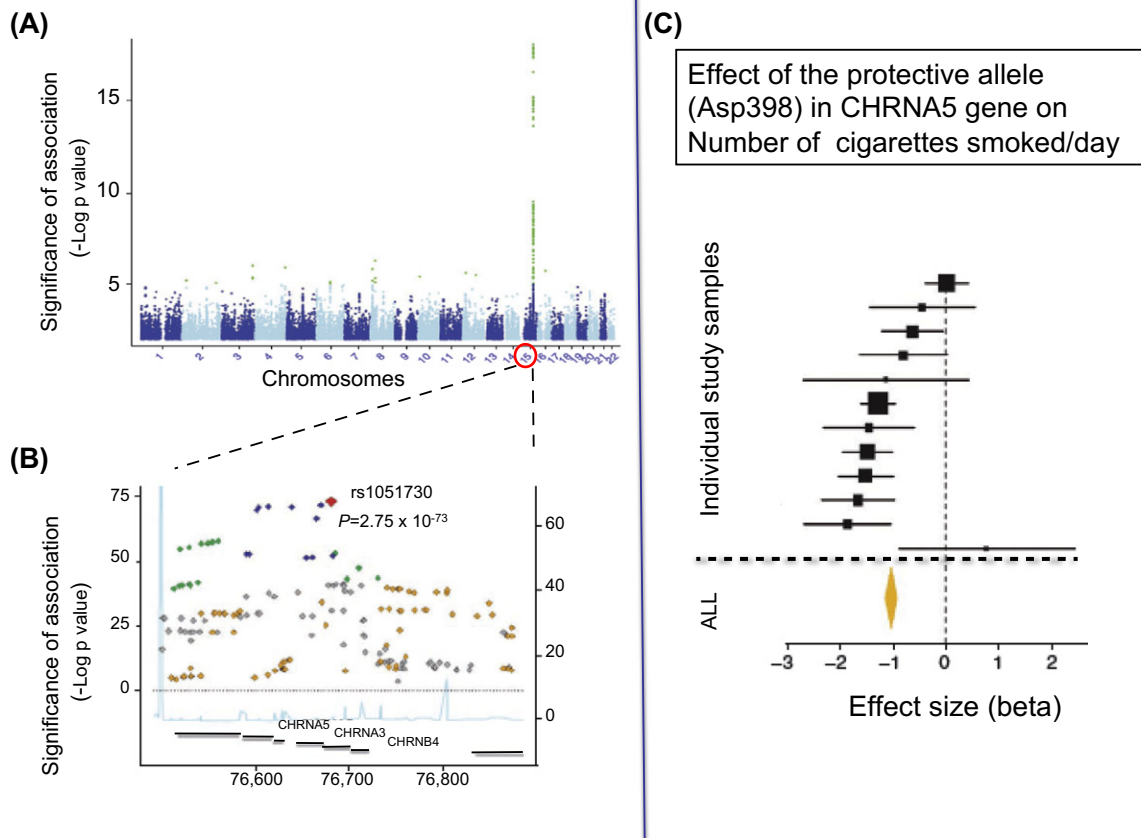

15q25 corresponding to the region where these three genes are located (Figure 113-19A,B).

Two SNPs in this region that have been repeatedly associated with smoking are the nonsynonymous (aspartic acid, Asp (D), to asparagine, Asn (N); rs16969968) SNP at codon 398 of *CHRNA5* and a synonymous SNP (rs1051730) in *CHRNA3*. These SNPs are in strong linkage disequilibrium with each other. The *CHRNA5* asparagine allele (Asn398) and the A allele at rs1051730 have been associated with nicotine dependence/heavy smoking (131,132), pleasurable response to smoking (133), decreased response to nicotine agonists in vitro (136), smoking quantity (134), smoking persistence and increased susceptibility to develop lung cancer and vascular disease among smokers (134,137,138). According to a recent meta-analysis, each copy of the A allele at rs1051730 accounts only for ~0.5% of the variance in number of cigarettes smoked per day. Nevertheless, the overall  $p$  value for this large meta-analysis including >74,000 participants was  $\sim 10^{-73}$ , making this finding one of the most consistent across the entire panorama of genetic-association studies on human behavior (139) (Figure 113-20C). Potentially explaining the mechanism by which the Asp398Asn locus alters propensity to nicotine addiction, the asparagine allele was found to predict the strength of a brain circuit connecting the anterior cingulate to the ventral striatum (140). The anterior cingulate is a component of the limbic system involved in emotional modulation, and the ventral striatum is a principal reward region of the brain. Strength of this circuit itself was associated with nicotine dependence, and this genotype predicted the circuit strength in both smokers and nonsmokers.

For alcoholism, results from GWASs have been less convincing. None of the alcohol dependence GWAS has yet yielded a finding that reached genome-wide significance (141–144). Larger studies and meta-analytic approaches are likely to change this picture. In addition, GWASs performed on alcoholism-relevant intermediate phenotypes are underway. For example, a GWAS on variation in the electroencephalogram yielded genome-wide significant loci (123).

### 113.3.3 Rare and Common Variants

The focus of genetic studies of addiction, as well as other common disorders, have been common genetic variation, namely, variants with a MAF >1%. The idea behind these studies is the common disease/common variant (CDCV) hypothesis according to which common alleles of ancient origin and with small to moderate effect lead to susceptibility to common disorders. The success of GWASs in explaining the genetic variance of common diseases is to some extent tied to the validity of this hypothesis. Consistent with the hypothesis, the effect sizes of loci detected by GWASs have generally

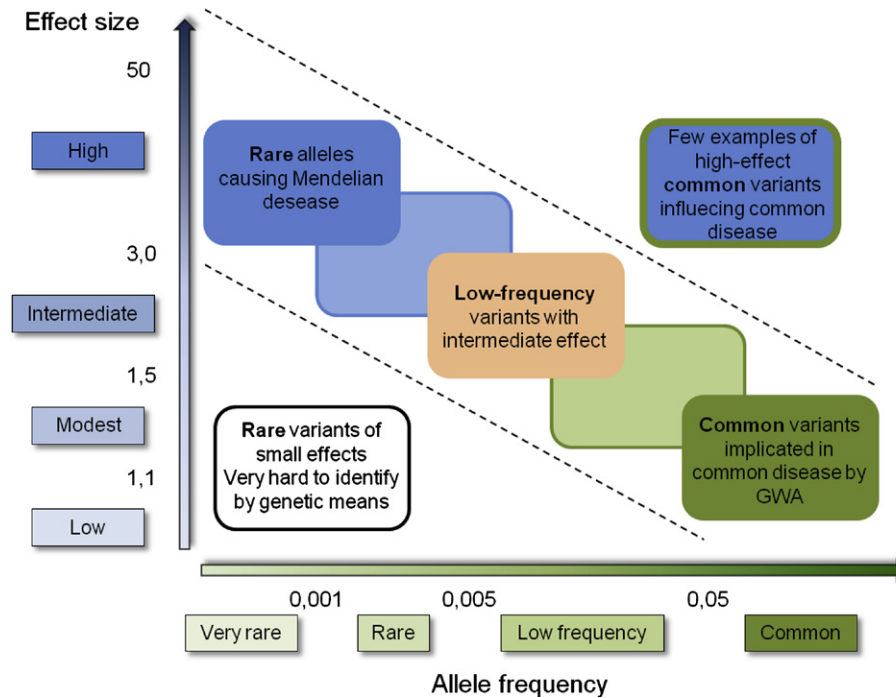

**FIGURE 113-19** Association between smoking behavior (number of cigarettes smoked per day, CPD) and genetic variation within the *CHRNA5-CHRNA3-CHRNA4* gene cluster on chromosome 15q25. (A) In the Manhattan plot, level of significance (–log  $p$  value) of association to SNPs covering 22 autosomal chromosomes is shown. SNPs reaching genome-wide significance ( $p < 10^{-8}$ ) are in green. Results show a strong signal of association within chromosome 15. (B) The chromosome 15 region contains the *CHRNA5-CHRNA3-CHRNA4* gene cluster. (C) The most significant SNP within this region is rs1051730, which is highly correlated with a nonsynonymous (aspartic acid (Asp) to asparagine (Asn)) SNP (rs16969968) at codon 398 of the *CHRNA5* gene. The asparagine allele at this locus is associated with increased risk of becoming a heavy smoker. In contrast, the aspartic acid allele is protective, as shown by the negative effect size (beta). (Adapted with modification from (159,160)).

been small, with a mean genotype relative risk (GRR) of 1.25 for all complex disorders (145). However, the total genetic variance accounted for has been less than half of what is estimated to exist, and usually less than 10%, the amount depending on the disease and the intensity with which it has been studied. It is perhaps dangerous to extrapolate, but this may indicate that common variants may not explain most of the heritability of common diseases. Recent evidence suggests that rare variants with larger GRR are likely to contribute to genetic vulnerability to common diseases (for review see Reference (146). Indeed associations with multiple rare variants with moderate-to-large effect sizes (GRR of approximately 10) have been recently reported for schizophrenia and autism (147,148). A rare stop codon was detected in the serotonin receptor 2B gene (*HTR2B*) that can lead to severe impulsivity (149). Some of these variants appear to be associated with severe forms of disease and are thought to be of recent origin and to some extent de novo. Consistent with that, the *HTR2B* stop codon was restricted to the Finnish population and is in that sense a “founder mutation,” and an *MAOA* stop codon that

also influences impulsivity, was restricted to only one Dutch family.

The contribution of rare variants in common diseases is still largely unknown. However, recent advances in sequencing technologies enable the sequencing of genome, exome (the expressed portion of the genome) or targeted gene panels at low cost, and have opened the way for extensive searches for rare variants. The probability of discovery of variants influencing vulnerability to addiction is dependent on their effect size and frequency, and the number of individuals studied (Figure 113-20).

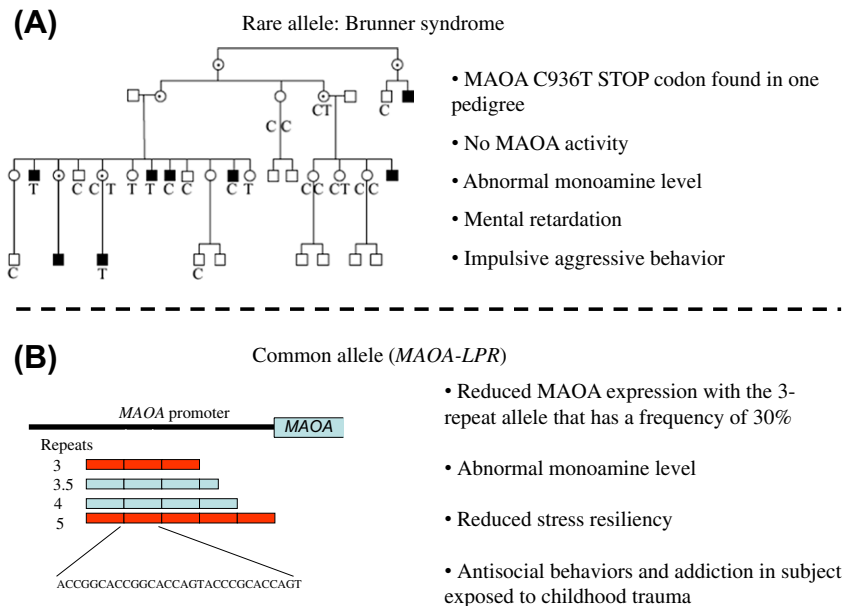

However, as illustrated by the discovery of the *MAOA* and *HTR2B* stop codons in impulsivity, the sequencing-based discovery of rare variants can be augmented by the study of genetically related individuals in families and founder populations and by the sequencing of individuals who are phenotypically extreme. It is also likely that statistical strategies will be further developed to pool effects of multiple rare variants at the same gene. Rare and uncommon functional variants may coexist at the same gene. The *MAOA* gene is an interesting example highly relevant to the addictions (Figure 113-21).

**FIGURE 113-20** Feasibility of identifying genetic variants by risk allele frequency and strength of genetic effect (odds ratio (OR)) in case/control samples. Effects of common variants (MAF > 5%) with low effect sizes (ORs approximately below 1.5) can be detected in very large samples. Effects of rare variants of large effect size may also be detected. Alternative strategies for rare variants include families, founder populations and “extreme” phenotypes. Of note, effects of rare variants with small effect size will be very difficult to identify. (*Adapted with modification from Manolio et al. (161)*).

MAOA is an X-linked gene encoding MAOA, a mitochondrial enzyme that metabolizes monoamine neurotransmitters including NE, DA and serotonin. MAOA knockout mice have higher levels of these neurotransmitters and manifest increased aggressive behavior and stress reactivity (150). In the human, different MAOA genetic variants impair MAOA activity to different degrees, and the reduction in enzyme activity appears to parallel the effect on behavior. In 1993, Brunner et al. (151) reported a Dutch family in which eight males were affected by a syndrome characterized by borderline mental retardation and impulsive behavior including impulsive aggression, arson, attempted rape, fighting, and exhibitionism (Figure 113-21A). The cause was a stop-codon variant in the eighth exon leading to complete and selective deficiency of MAOA activity, with an X-linked pattern of transmission. Discovery of this mutation led to attempts to identify it in other individuals with behavioral dyscontrol, including individuals accused of serious crimes. However, and despite intensive effort, the stop-codon variant was not found in other individuals, and thus represents an example of a rare, private allele. More recently, a common MAOA polymorphism influencing MAOA transcription was discovered (152). This locus, termed the MAOA-linked polymorphic region (MAOA-LPR), is a VNTR located approximately 1.2kb upstream from the MAOA start codon and within the gene’s transcriptional control region (152)

(Figure 113-21B). Alleles at this VNTR have a different number of tandem copies of a 30-bp sequence, with the three- and four-repeat alleles being by far the most common. Alleles with four repeats are transcribed more efficiently than alleles with three copies of the repeat, and therefore lead to higher MAOA enzyme activity (152). In a longitudinally studied cohort of boys, Caspi et al. (153) found that MAOA-LPR moderated the effect of childhood maltreatment on vulnerability to develop antisocial behavior. In this study maltreated boys with the low-activity genotype were more likely to develop antisocial problems later in life than boys with the high-activity genotype. Meta-analysis of several studies that represent attempts at replication revealed a significant pooled  $G \times E$  effect for MAOA and stress. A similar MAOA  $\times$  stress interaction appears to occur in women, although of course a much smaller percentage of women are homozygous for the low-expression allele (males being hemizygous for MAOA). In a sample of Native American women, the effect of childhood sexual abuse (frequent among women in this and other populations) on risk of developing alcoholism and APD was contingent upon MAOA-LPR genotype (44). Sexually abused women homozygous for the low-activity MAOA-LPR allele had high rates of both disorders, and heterozygous women displayed an intermediate risk pattern. However, in the absence of childhood sexual abuse, there was no relationship between MAOA genotype and these disorders.

**FIGURE 113-21** Rare and common variants within MAOA. (A) Pedigree of a Dutch family with eight males affected by Brunner syndrome, X-linked behavioral dyscontrol caused by a stop codon (C936T) in monoamine oxidase A that cause complete lack of MAOA activity (151). (B) The MAOA-linked polymorphic region (MAOA-LPR) is a common variable-number tandem repeat (VNTR) located approximately 1.2 kb upstream from the MAOA start codon and within the gene's transcriptional control region. Alleles at this VNTR have a different number of tandem copies of a 30-bp sequence, with the three- and four-repeat alleles being by far the most common. Alleles with three repeats are transcribed less efficiently, leading to lower MAOA enzyme activity.

MAOA G×E has also been studied in animal models. These are useful because of the ability to control stress exposures and many other environmental variables. In the Rhesus macaque (*Macaca mulatta*) early life stress exposure, particularly early separation from the mother, leads to dyscontrolled behavior and enhanced stress response later in life. The behaviors observed in the stressed animals include increased alcohol consumption, higher impulsive aggression, incompetent social behavior and serotonin dysfunction, and increased behavioral and endocrine responsivity to stress (for review see Reference (154)). Remarkably, an orthologous (same evolutionary origin and same function) VNTR polymorphism is also found in the promoter region of MAOA in the rhesus macaque. Also similar to the human, the lower activity allele predicts aggressive behavior in these animals, and the association is dependent on whether the monkey had been separated from its mother (155).

Impulsivity, “action without foresight,” is an important contributor to addictions of all types, and apparently there are many more rare and uncommon variants contributing to impulsivity that remain to be discovered. An example of a genetic variant leading to impulsivity, even severe impulsivity associated with criminal violence, is a stop codon in the HTR2B serotonin receptor (149). This stop codon, Q20\*, has an allele frequency of 1.2% in Finns (and >100,000 carry it), but is population specific. In that regard it can be regarded as relatively common, or rare, depending on whether one is taking a population-specific or world view. The variant was discovered by sequencing phenotypically extreme Finns. All

the sequenced probands were alcoholic violent offenders. Carriers of the stop codon who had committed violent crimes did so while inebriated with alcohol, and there were other risk factors—the stop codon alone was not sufficient. Mice with the *htr2b* gene knocked out are more novelty seeking and impulsive. For example, in a delay discounting task these *htr2b*–/– mice were less able to tolerate delay in order to receive a large reward. Just as genes such as NPY that alter resiliency play a role in addictions, the HTR2B stop codon and the variants at MAOA may be only the precursors of a larger pattern of genes influencing impulsivity.

### 113.4 TREATMENT OF ADDICTIONS

Treatment of addiction is enormously beneficial, in the same sense as it is also worthwhile to treat other diseases such as cancer, where success rates are substantially less than perfect, where there may be relapse, and where volition and lifestyle choices also play a powerful role in etiology and outcome. The maintenance of abstinence for multiyear periods has enormous benefits to the individual, family, and community. The complex nature of addictions makes their etiology difficult to comprehend, but paradoxically creates a broad range of opportunities for interventions that can be used often in combination. Effective interventions extend from the spiritual and religious to drug therapies that ease withdrawal, block the action of an addictive drug (antagonist therapies), substitute for the addictive agent (agonist therapies), or reduce symptoms such as anxiety and depression

**FIGURE 113-22** Genetic variation within the *OPRM1* gene and treatment response to naltrexone. The *OPRM1* Asp40 allele predicted good clinical outcome in patients treated with naltrexone (an antagonist of the mu-opioid receptor), shown in gray, as compared to patients treated with placebo (156).

that accompany long-term withdrawal and can trigger relapse. Lastly, the identification of genes altering the liability to addiction and ability to recover are a major focus for genetic studies, because these could provide new therapeutic targets and an ability to individualize treatment (so-called personalized medicine). One of the first examples of pharmacogenetic prediction of treatment response in the addictions is a common functional missense variant of the mu-opioid receptor (*OPRM1* Asn40Asp) (Figure 113-22)

In several studies, naltrexone, a mu-opioid receptor antagonist, was observed to augment abstinence and good therapeutic outcome in recovering alcoholics. Carriers of the Asp40 allele appear to be highly likely to show clinical improvement when treated with this drug (Figure 113-22), encouraging the idea that the treatment of this large clinical population can be better targeted (156,157).

### 113.5 CONCLUSION

Substance use disorders are common, chronic, and relapsing diseases that develop through a multiple-step process. The impact of addictions on morbidity and mortality is high worldwide. Twin studies have shown that addictions are among the most heritable of psychiatric diseases, with heritabilities ranging from 0.39 (hallucinogens) to 0.72 (cocaine). Twin studies indicate that genes influence each stage of psychoactive substance use, from initiation to addiction, although the genetic determinants may differ for each stage. Addictions are by definition the result of the gene  $\times$  environment interaction. These disorders, which are in part volitional, in part inborn, and in part determined by environmental experience, pose the full range of medical, genetic, policy, and moral challenges. Gene discovery is being facilitated by a variety of powerful approaches, but is

in its infancy. It is not surprising that the genes discovered so far act in a variety of ways: via altered metabolism of the drug (the alcohol metabolic gene variants for alcohol), altered function of the receptor of the drug (the nicotinic receptor for nicotine), and general mechanisms of addiction (genes such as MAOA and the serotonin transporter that modulate stress response, emotion and behavioral control).

## Biographies

**Dr David Goldman** received his BS from Yale University in 1974. He received his MD degree in 1978 and completed residency training in psychiatry in 1979, both at the University of Texas Medical Branch. Dr Goldman joined the NIAAA in 1979 and has been Chief of the Laboratory of Neurogenetics since 1991. Throughout his career, Dr Goldman has focused on the identification of genetic factors responsible for inherited differences in behavior, and he has authored over 300 papers. This laboratory has recently completed projects including functional genomics studies identifying genetic variants that alter in vitro and in vivo response. These include multilevel studies on NPY, GCH1 and the serotonin transporter. His laboratory is currently exploring the genetics of alcoholism and related psychiatric diseases, and is well-known for his work identifying effects of functional genetic variants on intermediate phenotypes for complex behavioral diseases. Awards that Dr Goldman has received include NIMH Director's Honor Award for genetic factors that may alter susceptibility to schizophrenia, James Isaacson Research Award, International Society for Biological Research on Alcoholism, and the NIH Director's Award for the years 2002 and 2010. Dr Goldman is author of, "Our Genes, Our Choices."

**Dr Francesca Ducci** received her MD degree in 2001 and completed her residency training in 2004, both at the University of Pisa, Italy. Dr Ducci worked as postdoctoral visiting fellow from 2004 to 2008 at the Laboratory of Neurogenetics of NIAAA. In 2008 she moved to London where she is working as academic clinical lecturer at the Institute of Psychiatry, Kings College and at the Department of Epidemiology and Biostatistics of Imperial College. Her research interest is focused on the study of genetic and environmental factors that promote the early initiation of addictive substance use and the later development of Substance Use Disorders. Dr Ducci has authored more than 30 papers. These include studies on the effects of genes encoding for nicotine receptors, MAOA, and dopamine receptors on vulnerability to alcoholism and nicotine dependence. Awards that Dr Ducci has received include the American college of Neuropsychopharmacology travel award, the International Behavioral and Neural Genetics Society Outstanding Junior Faculty Travel Award and the Early Career Investigator award at the World Congress of Psychiatric Genetics. Dr Ducci is also working as specialist registrar in general adult psychiatry at the South West London and St George's Mental health trust.

**Dr Paola Landi** received her MD degree from the University of Pavia, Italy in 2008. She is currently attending her final year of residency training in psychiatry at the University of Pisa, Italy. She is also attending her last year at the school of Cognitive-Behavioral Psychotherapy in Milan. Her main research interest is to explore emotional processing in psychosis.

### 114.1 EMBRYOLOGY

Neurulation is the critical morphogenetic event occurring during the fourth week of human gestation, converting the previously developed neural plate into the ectoderm-covered neural tube that will eventually differentiate into the brain and spinal cord. Genetic regulation of the events involved in mammalian neural tube morphogenesis is a complicated process that involves a multitude of genes. These genes have vital functions in a range of biological activities that are thought to include signaling molecules, transcription proteins and factors, cytoskeletal and gap junction proteins, growth factors, and tumor suppressor genes (1–4). For decades, the process of neural tube closure has been oversimplified by authors who suggested that the neural plate is merely a sheet of cells that rolls into a hollow tube that closes continuously in a “zipperlike,” manner. This description leaves out the intricacies of cell migration and alterations in cellular morphology that underlie successful development and closure of the neural tube (5).

At the earliest stages of neural tube development the epithelia of the two-layered embryo is induced by signaling molecules to thicken and form a neural plate that is anchored over the notochord. The neural plate subsequently bends at the midline or medial hinge point (6). In a general sense, the lateral portions of the neural plate elevate, and the rostral regions of the neural folds bend inward at the dorsolateral hinge points (7–10). In addition to the bending motions, the movement of the neural folds is aided by the narrowing and lengthening of the cells of the neural plate. Two additional processes are fundamental to the creation and fusion of the neural tube. The first is

apical constriction, whereby columnar epithelial cells are converted into wedge-shaped cells by cytoskeletal elements (11–13). The second is convergent extension, whereby the flat sheet of epithelial cells is remodeled, via intercalation, into a longer, narrower configuration (14,15).

The neural tube, formed by the cell shape changes and movements described above, ultimately fuses at several discrete points. In the mouse, the neural folds begin to fuse at the extreme caudal portion of the hindbrain (actually in the midcervical portion of the embryo) at gestational day embryonic day (E) 7.0 (closure I). A second site at the forebrain–midbrain boundary begins to close at E8.0 (closure II). At E9.0, the neural plate at the rostralmost position of the developing embryo fuses to form the anterior forebrain (closure III), and by E9.5, the neural tube fuses in the midbrain–hindbrain junction (closure IV). Fusion from closure sites II and IV proceeds bidirectionally, until the two sites meet and complete the formation of the cranial neural tube. By E10.0, the neural tube is closed with the exception of the caudal end where the posterior neuropore becomes increasingly smaller and ultimately disappears.

The process of neural tube closure in humans is similar to that of the mouse. It has been proposed that human embryos have two successive sites of fusion of the neural folds, one in the rhombencephalic region and one in the prosencephalic region, adjacent to the chiasmatic plate (16). Fusion of the neural tube is initiated from site 1 at the level of somites 2 and 3, when 4–6 somitic pairs are present, and extends bidirectionally to involve the rhombencephalic and spinal levels, and ultimately the cervical, thoracic, mesencephalic, and prosencephalic levels (16). Fusion from site 2 is unidirectional (caudad

only). Accessory loci of fusion may also be present in older, Carnegie stage 10 embryos. However, the presence and location of such loci are inconsistent and their importance in neural tube closure remains speculative (16).

In humans, fusion of the neural tube initially involves surface ectoderm, followed by the neural ectoderm, and subsequently the interposition of mesenchyme, which is derived from the primitive streak/node and is responsible for elevation of the neural folds. The presence of mesenchyme in the crest at Stages 9 and 10 is likely to be a requirement for normal neurulation, and thus impairment of the primitive node and streak could lead to neural tube defects (NTDs). The observed fusions terminate in two neuropores, one rostral and one caudal. In humans, primary neural tube closure is thought to be complete when approximately 19–20 somite pairs have appeared (Carnegie stage 12) (16). The secondary neural tube develops between Carnegie stages 13–20, by a process of differentiation and canalization with the primary neural tube (17).

## 114.2 DEFINITION

Abnormalities of neural tube closure may result from alterations in any of the processes that are involved in the formation of the primary neural tube (e.g. elevation and bending, apical constriction, convergent extension). As these processes are under the control of a multitude of genes, the molecular basis of neural tube closure defects is likely to be quite heterogeneous. Indeed, in the mouse, defects of neural tube closure have been shown to result from genetic mutations affecting cell proliferation and apoptosis, convergent extension, elevation/apposition of the neural folds, and neural tube fusion (9,18–20).

Despite the complexity of the processes that are required for normal neural tube closure, the gross phenotypic consequences of abnormalities in these processes are relatively homogeneous. In general, failure of neural tube closure is associated with defects in the overlying bony structures (i.e. cranial vault and neural arches) such that the underlying neural tissue is exposed to the body surface. Consequently, defects of primary neural tube closure are often referred to as “open” NTDs. Further classifications of the open NTDs are based on the location and extent of the defect.

NTDs that are restricted to the cranial region of the neural tube are referred to as anencephaly. This condition is characterized by the absence of the cranial vault and absent or markedly diminished cerebral hemispheres. In addition, the cerebellum is usually absent and the brain stem may be hypoplastic. Anatomically, anencephaly is classified as holocrania if the defect involves the foramen magnum and merocrania if the foramen magnum is not involved. Most fetuses with anencephaly are aborted or stillborn; however, a small proportion of anencephalic infants is live born and can survive for short periods without significant medical support.

Neural tube closure defects that are restricted to the caudal portion of the neural tube are referred to generally as spina bifida or specifically as meningocele. This condition is associated with bony defects in the overlying neural arches, through which the meninges and spinal cord tissue are exposed to the body surface. Clinically, meningocele may be further characterized by the anatomic level and the extent of the lesion. The majority of fetuses with meningocele are live born and, with proper treatment, survival into the adult years is common. Failure of neural tube closure over the entire body axis, or craniorachischisis, is a lethal condition.

In addition to the open NTDs, there are also a number of “closed” or skin-covered conditions that involve the neural tube, including encephalocele, iniencephaly and lesions often referred to as occult spinal dysraphisms such as meningocele (that may be partially skin covered), spinal lipomas (lipomyelomeningocele or lipomeningocele), myelocystocele, split cord malformations, and various forms of sacral agenesis. In general, these conditions are not thought to result from defects in primary neural tube closure but may result from defects in secondary neural tube development. Nonetheless, there is evidence that open and closed NTDs may have some common etiological underpinnings. For example, families segregating both open and closed NTDs have been reported (21,22) and declines in the prevalence of encephalocele, as well as anencephaly and spina bifida, have been reported following folic acid fortification of the food supply in Chile (23–25).

## 114.3 PREVALENCE

As a group, the open NTDs (anencephaly, meningocele or spina bifida, and craniorachischisis) are relatively common malformations. However, the true incidence of these conditions is unknown, since only a proportion of affected conceptuses survive to a stage where their NTD is likely to be recognized. The prevalence of these conditions at birth is also difficult to estimate accurately, since some affected fetuses are identified and electively terminated in the prenatal period (26–31) and others are stillborn. Hence, estimates of the birth prevalence for these conditions may be influenced by the ascertainment methods (e.g. active vs passive surveillance), source documents (e.g. birth certificates vs chart review), and inclusion criteria (e.g. live born, stillborn, elective terminations) (32–35).

Despite differences between studies that make it difficult to directly compare estimates, several characteristic features of the prevalence of NTDs have been identified. In general, the prevalence of spina bifida is higher than that of anencephaly and the prevalence of craniorachischisis is much less than that of either spina bifida or anencephaly. In addition, the prevalence of NTDs is higher in females than in males (36) and varies by race/ethnicity (37), across regions, and over time (38,39). Moreover,

data from countries that have implemented mandatory folic acid food fortification programs indicate that the prevalence of NTDs is reduced by approximately 50% following such fortification (40).

## 114.4 RISK FACTORS

The open NTDs are recognized as being etiologically heterogeneous. A small proportion of affected individuals have an associated chromosomal or Mendelian malformation syndrome (41) and there are rare families in which NTDs segregate in patterns consistent with X-linked or autosomal recessive inheritance. In addition, a small proportion of cases can be linked to an established risk factor. The most notable of these factors are maternal pregestational insulin-dependent diabetes and maternal use of medications, in particular, specific anti-convulsant drugs.

### 114.4.1 Maternal, Insulin-Dependent Diabetes

The teratogenic potential of maternal pregestational diabetes is well established and includes a 2- to 10-fold increase in the risk of central nervous system malformations (including NTDs) among the offspring of affected women, relative to the general population (42). Moreover, the level of maternal periconceptional glycemic control has been associated with the risk of NTDs in the offspring of diabetic women (42–44).

As human embryos lack pancreatic function until after the seventh week of gestation, the teratogenic effect of maternal diabetes may be due to embryonic exposure to elevated glucose concentrations. In rat embryos, elevated glucose concentrations are known to induce oxidative stress and deplete inositol stores (45) and inositol supplementation has been found to be protective against posterior NTDs in a murine model system (46). In addition, inositol metabolism is impaired in three NTD mouse mutants (47). Although it remains to be seen whether inositol can confer protection against NTDs in humans, an initial investigation provided no strong evidence of an association between maternal myoinositol intake and risk of NTDs in humans (48).

Animal models have suggested that the association between maternal diabetes and NTDs may be mediated by the paired box (Pax) family of transcription factors (49,50). This family of genes plays critical roles in development. In humans, mutations in PAX3, which is expressed in the neuroepithelium, neural crest, and somatic mesoderm, are associated with Waardenburg syndrome, a condition that includes an increased risk of NTDs. Moreover, mouse strains carrying null mutations for the Pax-3 gene develop NTDs similar to those that occur in the embryos of diabetic mice, and diabetic mice heterozygous for a Pax-3 mutation demonstrate elevated rates of NTD-affected pregnancies compared to diabetic

mice lacking this mutation (51). Furthermore, when hyperglycemia is artificially induced in dams of inbred strains, Pax-3 expression is reduced, leading to neuroepithelial apoptosis and ultimately NTDs. Similar results are obtained in vitro through treatment of explants with glucose (49,52–54). Although an association between PAX3 and nonsyndromic NTDs has not been found in human studies (55–59), this association has not been fully investigated.

Rappaport and Smith (60) recently attributed 70–90% of the risks for chronic disease including adverse pregnancy outcomes to environmental factors. They brought to light the importance of understanding that “toxic effects are mediated through chemicals that alter critical molecules, cells, and physiological processes inside the body.” This would include the production of inflammatory molecules, reactive oxidative compounds, lipid peroxidation molecules and others (60). Environmental exposures including small particle air pollution and heavy metals such as arsenic and cadmium pose real threats to human health via their direct absorption into systemic circulation and their linkage to the pathogenesis of metabolic diseases, including diabetes (61–63). Xu and coworkers (64) demonstrated in genetically sensitive P47Phox mice that chronic exposure to PM2.5 resulted in heightened inflammatory responses and the formation of reactive oxidative species. Environmental arsenate exposure has been shown to directly affect both the maternal and embryonic glucose levels in an experimental mouse model system, paralleling the situation in maternal type 2 diabetes (39). The maternally administered arsenate crossed the placenta and produced a well-described pattern of fetal malformations that are primarily characterized by NTDs (38,65). Work by Salbaum and Kappen (66) further demonstrated that maternal diabetes alters the regulation of critical embryonic genes. This dysregulation of embryonic genes may include epigenomic changes via deregulated expression of chromatin-modifying factors. Using a mouse model of streptozotocin-induced diabetes, the prevalence of NTDs was tripled when the diabetic mice were maintained on a low-folate diet (67).

### 114.4.2 Maternal Use of Medications

The anticonvulsant drug valproic acid (VPA; Depakene, Abbott Laboratories) has been directly implicated as a potent neural tube teratogen. Among women taking VPA (alone or in combination with other anticonvulsant medications) the risk of having a pregnancy affected with spina bifida may be as high as 1–2%, whereas the risk of anencephaly does not appear to be increased (68–72). In humans, in utero VPA exposure has also been associated with craniofacial, cardiovascular, and skeletal defects (73–77). However, only a small percentage of VPA-exposed fetuses present with spina bifida or other malformations, suggesting that there may be genetically mediated differences in sensitivity to VPA teratogenicity.

Studies in murine model systems have revealed strain differences in NTD susceptibility to single maternal intraperitoneal (IP) injections of 600 mg/kg VPA on E8.5 (78). To identify the chromosomal locus associated with sensitivity to VPA-induced NTDs, a genome-wide linkage analysis was performed using SWV and C57 fetuses. The result of these analyses suggested that an autosomal recessive locus, plus a gender-related effect or an overall X-chromosome effect, determine sensitivity to VPA-induced exencephaly. Subsequent analyses identified a major locus for VPA-induced exencephaly linked to D7Mit285 ( $p < 2 \times 10^{-6}$ ) (79). This marker showed the most significant linkage in the secondary screen ( $p < 0.005$ ); therefore, additional BC1 samples were genotyped. This analysis of the BC1 panel (131 NTD pups total) yielded a probability of  $p < 2 \times 10^{-6}$ , greatly exceeding the threshold for highly significant linkage. A total of 13 additional markers flanking D7Mit285 were genotyped, which confirmed this observation and further refined the mapping of the sensitivity trait. Examination of recombination events showed that this gene is located between D7Mit285 and D7Mit101, which are 3.3 Mb apart. Within this region is the Acyl-CoA synthetase medium-chain (ACSM) gene family, which plays a role in conjugating VPA with coenzyme A before the molecule enters  $\beta$ -oxidation. Given this important biochemical role and the strong linkage data, the ACSM genes are leading candidates for a significant role regulating susceptibility to VPA-induced NTDs.

There are several other possible theories to explain a genetically regulated mechanism for susceptibility to VPA-induced NTDs, including the inhibition of folate metabolism by VPA (80,81). Specifically, VPA interferes with selected steps in the folate pathway, which may decrease the rate of methylation of essential, developmentally regulated genes during critical periods of embryogenesis. This could significantly enhance the sensitivity of the embryos to specific malformations. However, definitive interactions between folate metabolism, VPA therapy, and gene regulation have yet to be demonstrated.

Valproic acid may also influence neural tube development via its action as a potent inhibitor of histone deacetylases (HDACs) (82–85). Class I and II HDACs are involved in histone modification and therefore play a role in the regulation of gene expression. Specifically, histone acetylation is often related to transcriptional activation, whereas HDACs are capable of down regulating gene expression (86). The inhibition of HDACs by VPA has been associated with teratogenicity in a *Xenopus* model system (87). Thus, it is possible that post-translational gene modification is compromised by VPA exposure, which inhibits HDACs and limits the availability of folate molecules (87) and thereby increases the risk of NTDs. VPA inhibits HDAC activity most likely by binding to the catalytic center and blocking substrate access and causing hyperacetylation of the N-terminal

tails of histones H3 and H4 in vitro and in vivo. VPA serves to relieve the repression of transcription factors such as PPAR $\delta$ , which recruit HDACs. The inhibitory effect of VPA on HDACs was first discovered in HeLa cells (87). Because HDACs play important roles in transcriptional regulation and pathogenesis of cancer, VPA as an HDAC inhibitor, is considered a candidate drug for cancer therapeutics (82,87,88). In several cell lines, a therapeutic dose of VPA reduces proliferation, morphological changes, and marker gene expression, similar to the HDAC inhibitor TSA (5).

The literature concerning the teratogenic potential of the frontline antiepileptic drug carbamazepine (CBZ) is significantly more limited than the literature that exists for VPA (70,89–91). Nonetheless, it is clear that the risk for NTDs in infants exposed in utero to CBZ approaches that of VPA. Consistent with earlier reports, Hernandez-Diaz and colleagues (92) observed a seven-fold increased risk of NTDs in the offspring of women who used CBZ during pregnancy, compared with the offspring of women who did not. Moreover, based on a meta-analysis of the existing literature there was evidence (based on 1255 prospectively ascertained gestations exposed to CBZ) of a significantly increased risk of congenital malformations, primarily NTDs, amongst CBZ-exposed infants. No additional increase in risk was observed among the offspring of women who took CBZ and one additional anticonvulsant medication. However, when CBZ exposure occurred in the presence of two or more additional anticonvulsants, the risk to the exposed infant was significantly elevated relative to that of infants exposed to CBZ alone (58).

Similar to VPA, CBZ and its major metabolite, CBZ-10,11-epoxide, are both able to inhibit HDACs (86). Thus, it is possible that in utero exposure to CBZ inhibits embryonic HDACs, resulting in the repression of critical genes involved in neural tube closure. It has also been suggested that arene oxide intermediates are responsible for CBZ's teratogenicity. It is possible that the binding of a CBZ electrophile to a critical, developmentally regulated protein could compromise normal embryogenesis (93). There is an exhaustive literature suggesting that an inherited defect in epoxide hydrolase activity can place selected mother-offspring pairs at increased risk for antiepileptic drug-induced birth defects (94). Unfortunately, efforts to positively associate epoxide hydrolase activity with adverse CBZ pregnancy outcomes have not been reported to date.

It is also possible that, like VPA, CBZ influences the risk of NTDs via its role as a folic acid antagonist. Other folic acid antagonists, including aminopterin and methotrexate, have also been associated with an increased risk of NTDs in prenatally exposed infants. Moreover, relative to unexposed infants, infants who were prenatally exposed to any member of the group of folic acid antagonists including CBZ, phenobarbital, phenytoin, primidone, sulfasalazine, triamterene, and trimethoprim

were found to be at increased risk of NTDs, with the highest risks being observed for infants exposed to CBZ (OR = 6.9, 95% CI 1.9, 25.7) and trimethoprim (OR = 4.8, 95% CI 1.5, 16.1) (92). Furthermore, both dihydrofolate reductase inhibitors and drugs that influence folate concentrations through pharmacokinetic mechanisms appear to be associated with increased risk of NTDs (92,95).

Maternal use of other drugs/categories of drugs including opiod analgesics (96), selective serotonin reuptake inhibitors (97), sulfonamides (98) and nitrosatable drugs (99) has also been associated with the risk of NTDs in offspring. However, the reported associations tend to be weaker than those reported for VPA and CBZ and either many have not been the subject of replication or replication studies have provided conflicting results.

Although NTDs can occur as part of chromosomal or single gene disorders or as a result of teratogenic exposures, a specific causative agent cannot be identified for the majority of affected individuals. NTDs that cannot be linked to a specific cause are often referred to as being nonsyndromic and are thought to result from the cumulative effects of multiple genetic/environmental risk factors. Epidemiological investigations have implicated a relatively large number of variables as potential risk factors for nonsyndromic NTDs. Although many of the reported associations have been weak and difficult to replicate, there are several variables for which there is relatively strong evidence of an association with NTDs. In general, it appears that anencephaly and spina bifida share some, but not all, of these risk factors (100).

### 114.4.3 Family History

A family history of NTDs is one of the strongest risk factors for these conditions. The risk of NTDs in the siblings of affected individuals ranges from 3% to 8% and is consistently higher than that of the general population. An increase in the risk of NTDs has also been reported for second-degree and third-degree relatives of affected individuals.

### 114.4.4 Nutrition

Maternal intake of natural folate, or its synthetic form, folic acid, is the most widely recognized nutritional determinant of the risk of NTDs in offspring. Case-control studies, randomized clinical trials, and community-based interventions of vitamin supplements have demonstrated that failure to consume adequate amounts of folic acid or folic-acid-containing multivitamins increases the risk of having an affected child two to eightfold. Further evidence that maternal intake of folate/folic acid is causally related to NTD risk is provided by studies that demonstrate a dose-response relationship between the risk of having a pregnancy affected by an NTD and maternal folate intake/status

(101–103) and by the observed decrease in the prevalence of NTDs following mandatory folic acid food fortification programs in several countries (24,104–116). In the United States, estimates of the birth prevalence of spina bifida and anencephaly (including affected fetuses identified in the prenatal period) following mandatory folic acid food fortification (1999–2000) were 4.1 per 10,000 and 3.5 per 10,000, respectively (113). These are likely to represent some of the lowest NTD prevalence estimates for this period worldwide. At the other end of the spectrum, estimates of NTD prevalence (anencephaly and spina bifida combined) as high as 20 per 1000 births (117) have been reported in some regions of China.

The mechanism underlying the association between NTDs and folate has not been established. However, folate participates in two metabolic pathways that, if disrupted, could have an adverse effect on the development of the embryo. One of these pathways is important for nucleic acid synthesis, and the other for a vast range of methylation reactions. Disruptions in folate metabolism can also result in elevated homocysteine levels, which are teratogenic to the neural tube in some species (118).

There is also evidence that the risk of NTDs in offspring may be related to other aspects of maternal diet including vitamin B12 (119–123), choline (124,125) and zinc (126,127) levels as well as maternal glycemic index (44,101,128,129).

### 114.4.5 Obesity

The risk of having a child with an NTD increases with increasing maternal body mass index (BMI). Women in the highest BMI categories (usually defined as a prepregnancy BMI greater than 29 kg/m<sup>2</sup>) have a 1.5-fold–3.5-fold higher risk of having an NTD-affected child than women who have lower BMIs (130–138). It has been suggested that the increased risk of NTDs in the offspring of obese women may be attributable to hyperinsulinemia (130). This could provide a common explanation for the associations between NTD risk and maternal obesity and maternal pregestational diabetes, since hyperinsulinemia may coexist with both conditions.

The majority of studies linking NTD risk to maternal BMI have been based on data that were largely derived from Caucasian women of European ancestry. It is therefore of note that in a relatively large study conducted in China (*N*=511 NTD cases), the risk of NTDs was not increased in the offspring of obese women and was significantly lower in the offspring of overweight women as compared to the offspring of normal weight (139). As this study was conducted in a region of China that has a very high prevalence of NTDs, these findings could reflect differences in the underlying etiology of NTDs in this high-risk population (as compared to lower risk populations) or differences in the characteristics of obese women (e.g. nutritional status) across populations.

### 114.4.6 Hyperthermia

Clinical and epidemiological studies have shown an increased risk for NTDs, in particular anencephaly, in infants whose mothers were exposed to hyperthermia during the first trimester of pregnancy (37,140–146). As many as 10% of NTD-affected live births, and 14% of NTD-affected abortuses, may have been exposed to teratogenic levels of maternal hyperthermia during early pregnancy (144). In a study of 23,419 women, it was found that early hyperthermic exposure (i.e. sauna, hot tub, fever, or electric blanket) roughly doubled the risk of an NTD-complicated pregnancy, while exposure to more than one of these factors increased this risk by six-fold (143). Interestingly, among women who reported first trimester infection and fever in the National Birth Defects Prevention Study, the risk of anencephaly or craniorachischisis was significantly lower among the offspring of women who took acetaminophen as compared to those who did not (147).

In humans, the greatest hyperthermic risk is generally considered to be from maternal febrile illness. In a large, retrospective, population-based case-control study, maternal fever or febrile illness in the first trimester was associated with a twofold increased risk for an NTD pregnancy (148). However, the possibility that the increased risk was due to reporting bias cannot be completely discounted. Although the effects of hyperthermia are difficult to disentangle from those of the underlying illness (142,145,146), data from experimental animals support a direct relationship between maternal hyperthermia and NTD risk (149–152).

Evidence from animal model studies suggests that induction of NTDs through elevation of the maternal core temperature is an embryonic, not a maternal effect. This has been investigated by completely removing the rat embryos from maternal influence and exposing the explants to mild hyperthermic insult during the onset of neural tube closure. Embryos thus exposed displayed head and somite malformations, with nearly half of the exposed embryos being microcephalic (153). It appears that temperature and duration of exposure act together in a dose-response manner to induce NTDs in experimental animals (154). This provides an explanation for the failure of saunas to induce elevated rates of NTDs in Finnish women, who regularly indulge in saunas while pregnant (155). Consistent with this explanation, subjects in another study could not tolerate hot tub exposure long enough to elevate their core temperature to 38.9°C (156).

Interestingly, there are apparent similarities between VPA-induced and hyperthermia-induced exencephaly in animal models. Phenotypically, both teratogens are primarily associated with exencephaly, an anterior NTD, but may induce other forms of birth defects and homeotic transformations when the treatment regimen is slightly altered (117,150). In addition, the inbred mouse strain SWV/Fnn is highly susceptible to both

VPA-induced exencephaly and NTDs induced by maternal hyperthermia (11,19,157,158). Moreover, with both these teratogens, the embryos affected with NTDs have an insufficient proliferation of cells in the neural tube due to an embryonic cell cycle arrest (159), which may be accompanied by cell death (or apoptosis). These similarities suggest the possibility of a shared mechanism(s) underlying the teratogenic effects of VPA and hyperthermia. It is not known whether such mechanisms involve a common stress response reaction or a specific molecular pathway. However, given the dissimilarity of the physical nature between hyperthermia and VPA, the involvement of a general stress response reaction appears to be plausible.

Cells and tissues of essentially all eukaryotes respond the same way to a variety of stressful situations. Owing to the activation of heat-shock proteins following several types of environmental insult (including hyperthermia), an embryonic stress hypothesis has emerged (160). The hypothesis maintains that the induction of the heat-shock response in the mammalian embryo during the critical period of organogenesis can alter the established program of activation and inactivation of genes essential for normal fetal development, thus leading to anatomic malformations. However, direct genetic evidence for such a highly speculative mechanism of teratogenesis is lacking (79).

### 114.4.7 Reproductive Technologies

An association between maternal use of fertility drugs, in particular clomiphene citrate, and an increase in the risk of NTDs in offspring has been suggested. However, based on a pooled analysis of 10 epidemiological studies, the summary prevalence ratio for the association between NTD risk and clomiphene citrate was 1.08 (95% CI 0.76, 1.51) indicating that clomiphene citrate either does not elevate or only very modestly elevates the risk of NTD in the offspring of women who use this drug (161). More recently, it has been suggested that the risk of NTDs may only be increased in women who develop follicular cysts following treatment with clomiphene (162). However, this association remains to be confirmed in independent investigations.

It has also been suggested that there is an association between assisted reproductive technologies (i.e. in vitro fertilization/intracytoplasmic sperm injection) and the risk of congenital malformations, including NTDs (163,164). Furthermore, data from Sweden indicate that the risk of NTDs is three- to fourfold high in offspring conceived following in vitro fertilization as compared to the general population (165,166). However, a study of both in vitro fertilization and intracytoplasmic sperm injection found no evidence of an increased risk of NTDs (167). It is possible that at least some of the differences observed between studies are due to the inclusion of different assisted reproductive technologies that may

be associated with different risks for malformations in offspring (168).

#### 114.4.8 Autoantibodies to Folate Receptors

Evidence has emerged that maternal immunological responses can have substantive impact on embryonic development. When antibodies to rat placenta, kidney, heart, and other tissues are generated and administered to pregnant rats, they bind to the yolk sac and embryonic tissue and are believed to contribute to congenital abnormalities and embryonic death (169,170). It has been postulated that the antibodies binding to the yolk sac impair the delivery of nutrients to the embryo (170, 171). Further studies show that monospecific antibodies to folate receptors, also known as folate binding proteins, can bind in vivo to the membrane-bound receptors on embryonic and extraembryonic tissues, inducing resorptions and developmental defects by blocking cellular uptake of folate (172,173). Additionally, large doses of antiserum may cause immune-mediated damage to embryonic tissues (173).

Rothenberg and coworkers (171) reported the presence of autoantibodies to the folate receptor in 75% (9/12) of mothers who had given birth to NTD-affected infants, but in only 10% of mothers of nonmalformed infants. This study suggests that maternal autoantibodies, which bind to the folate receptor, may block the intracellular uptake of folate by target epithelial cells and cause NTDs. This observation could explain the beneficial effect of periconceptional folate supplementation. This finding was subsequently replicated in larger studies using midgestational serum samples (29 mothers of NTD cases and 76 control mothers) in California (174) and Norway (175), but was not replicated in the largest study (approximately 100 case and control women) that has been conducted (121). Clearly, there is still much to be learned about the role of immune factors in susceptibility to NTDs, including the role of maternal autoantibodies that block folate transport during development.

#### 114.4.9 Other Maternal Risk Factors

Other maternal factors of interest, which require additional research in order to establish their association with NTD risk, include diarrhea (176), dieting behavior (177), caffeine consumption (166,178), emotional stress (179), physical activity (180), social networks (181) and education (182).

#### 114.4.10 Environmental Exposures

While many environmental agents are suspected of possessing a teratogenic potential based on data from studies in animals, relatively few have been confirmed as human teratogens. This may be due to several factors, including

differences in dose: laboratory studies performed on mice generally utilize doses that are much higher than encountered by humans; exposure assessment: environmental exposures are more difficult to quantify in studies involving humans than in mice kept under laboratory conditions; and degree of experimental control: genetic and environmental differences that may influence disease susceptibility are more easily controlled in studies of laboratory animals than in studies of human populations. However, several environmental exposures have emerged as potential risk factors for NTDs.

Fumonisin is a family of mycotoxins produced by *Fusarium verticilloides*, which is commonly found as a contaminant of corn. The major isoform, fumonisin B1 (FB1), causes liver and kidney cancer in rodents (158) and may be a human carcinogen (183). In addition, FB1 appears to be teratogenic in laboratory animals (184–188) and is a suspected risk factor for human NTDs in populations consuming large amounts of fumonisin-contaminated corn products (189–191). Data from a study conducted along the Texas–Mexico border indicated that the risk of NTDs was increased in the offspring of women whose consumption of corn tortillas was moderate (301–400 tortillas during the first trimester) as compared to the offspring of women with low consumption (<100 tortillas) during the first trimester (OR=2.4, 95% CI 1.1, 5.3). Furthermore, in this same population, the maternal postpartum sphinganine:spingosine ratio (a biomarker of fumonisin exposure) was directly related to the risk of NTDs in offspring (192,193).

It has been proposed that FB1 may induce NTDs as a result of its ability to interfere with folate transport (189). Specifically, receptor-mediated folate uptake was found to be reduced by up to 50% in Caco-2 cells pretreated with fumonisin (194). Fumonisin disrupts sphingolipid metabolism by inhibiting ceramide synthases, which are critical enzymes involved in the de novo synthesis of ceramide from fatty acids and sphingoid bases (192,195,196). As this pathway is required for glycosphosphatidylinositol (GPI)-anchoring, fumonisin disrupts GPI proteins such as the folate receptors. This in turn disrupts the receptor's endocytic recycling (197) and the amount of the receptor available for substrate transport (189). Fumonisin's role in the disruption of folate transport and lipid rafts is further supported by rescue of fumonisin-exposed dams with gangliosides (10mg/kg) the day before, on, and the day following exposure (189). Thus, the disruption of sphingolipid-dependent processes appears to mediate fumonisin's wide range of biological functions, which may contribute to an increased risk for NTDs (185,188,195,198).

In several animal models, maternal oral fumonisin exposures have been largely unsuccessful in producing NTDs in offspring (33,199,200). However, fumonisin does produce NTDs and significant growth retardation in developing murine explants (36). In explants, the risk of exencephaly increases with increasing dose of fumonisin,

but the effects of fumonisin can be partially mitigated by the addition of folate to the growth medium (187). Murine studies also demonstrate that maternal IP dosing with fumonisin during neurulation induces exencephaly in LM/Bc/Fnn mice and that this effect of fumonisin can also be reduced by folate supplementation (185,186).

Exposures to metals may also influence the risk of NTDs. Periconceptional exposure to cadmium (201) and lithium carbonate (202) has been associated with NTDs in animal models. However, human studies have shown no increased NTD risk from exposure to tap water contaminated with a variety of metals including lead, calcium, magnesium, copper, lithium, zinc, nickel, selenium, mercury, chromium, silver, cobalt, cadmium, and molybdenum (203). Furthermore, studies of the association between zinc and NTDs in humans have provided conflicting results (24,79,126,127,204–210).

There are also data indicating a relationship between folate and iron. Specifically, iron can modulate the availability of folate, leading to symptoms of folate deficiency despite adequate folate intake and extracellular folate concentrations (211). Investigations have shed light on this relationship by demonstrating that the homocysteine remethylation pathway is regulated in part by serine hydroxymethyltransferase, the product of the SHMT gene that is regulated by the heavy-chain subunit of ferritin (212). It has also been suggested that lead may induce NTDs by reducing bioavailability of dietary zinc (181,207,210,213).

Inorganic arsenic (Asi) is a natural element found in the environment (drinking water, air, food) as arsenate (pentavalent, As (V)) or arsenite (trivalent, As (III)). Arsenic is used as a pesticide, herbicide, and even as a medication. An association between human exposure to Asi and various forms of cancer is well established (214), and it has been suspected that Asi is also a human teratogen (215). However, a conclusive association between Asi exposure and the occurrence of human malformations has not been established (216,217). Numerous animal studies have examined the role of arsenic-induced teratogenicity in various species using different chemical forms, routes of administration, and experimental designs. Although Asi was previously found to be teratogenic only when administered by injection and not as a result of oral or inhalation exposure, this is no longer the case. Hill and colleagues (38) orally intubated pregnant mice on embryonic day (E) 7.5 and E8.5 with 4.8, 9.6, or 14.4 mg/kg sodium arsenate. This treatment regimen produced a specific pattern of malformations, including neural tube and craniofacial defects. In addition, these effects were observed in multiple species with a typical dose response, indicating that Asi has a direct teratogenic effect (215,218,219).

Other environmental exposures of interest as potential NTD risk factors include organic solvents (220–222), air pollutants and in particular benzene (190,223), chlorination disinfection by-products in drinking water

(176,224–226), electromagnetic fields (227,228), proximity to hazardous waste sites (229,230) and pesticides (231–233).

#### 114.4.11 Occupational Exposures

There is considerable interest in the relationship between parental (maternal and paternal) occupational exposures and the risk of congenital malformations in offspring. Although paternal exposures are less commonly evaluated than maternal exposures, paternal exposures could influence the risk of birth defects in offspring via a direct effect on sperm DNA (mutations or chromosomal alterations), indirectly via transmission of agents in seminal fluid, or maternal exposure to agents brought home by father.

Paternal exposure to the herbicide Agent Orange has been associated with an increased risk of NTD in offspring, but this association is based on a very small number of affected offspring (234). A meta-analysis of relevant studies published between 1966 and 2008 indicates that, compared to the offspring of unexposed men, the risk of NTDs in the offspring of men exposed to Agent Orange is increased by approximately twofold (relative risk = 2.02, 95% CI: 1.48, 2.74) (235).

Other paternal occupations that have been associated with an increased risk of NTDs in offspring include technical, sales and administration; farming, forestry and fishing; and fabricators and laborers (risk was assessed relative to paternal managerial and professional occupations) (236) as well as occupations involving exposure to organic solvents (218,237). Additional studies are required to confirm these associations and determine the specific exposures that are associated with increased risk of NTDs in offspring.

Maternal occupation exposure to solvents has also been associated with an increase risk of NTD in the offspring of Mexican-American women (221,237). In addition, there is evidence that the risk of NTDs and other birth defects may be increased in women with occupational exposure to glycol esters (221), although several negative studies have also been published (7,238). Other maternal occupations that have been associated with an increased risk of NTDs in offspring include, but are not limited to, health care and cleaning (221).

#### 114.4.12 Genetics

Studies of the recurrence patterns in families ascertained through an individual affected with anencephaly or spina bifida indicate that these two conditions tend to cosegregate within families and are therefore, likely to share a common etiology. In addition, family studies have demonstrated that the relatives of an affected individual are at increased risk of having an NTD compared with the general population. The relative risk ratio (i.e. risk to relative vs. risk in general population) for the sib of an affected

individual is 30–50. This is much lower than the relative risks exhibited by Mendelian conditions and higher than expected for conditions that are determined solely by environmental factors (147). Hence, it is commonly believed that the risk of NTDs is determined by multiple risk factors, including both genes and environmental agents.

Epidemiological studies of potential environmental risk factors for NTDs have a relatively long history and have identified several factors (reviewed previously) that appear to be related to NTD risk. In contrast, the study of genetic risk factors for NTDs has a relative short history. Although traditional genetic linkage approaches (e.g. LOD score and affected relative pair analyses) have been applied to the study of other conditions since the 1980s, the data required by such approaches (i.e. DNA from multiple affected individuals within families) are largely unavailable for NTDs. Consequently, studies designed to identify genes that influence the risk of NTDs did not become feasible until the 1990s, when the Human Genome Project began to provide new information regarding the variability within the human genome. Such advances in our understanding of the human genome have provided new opportunities for studying the genetic contribution to conditions such as NTDs (e.g. case-control and family-based genetic association studies of non-Mendelian conditions).

The majority of the published genetic association studies of NTDs have focused on one or a few candidate genes that are involved in folic acid transport and metabolism, since maternal intake of folate/folic acid in the periconceptional period is significantly related to the risk of NTDs in offspring. Variants of several folate-related genes, including 5,10 methylenetetrahydrofolate reductase (MTHFR), methionine synthase (MTR), and methionine synthase reductase (MTRR), have been found to be associated with the risk of NTDs in one or more studies. These studies have provided evidence that both the maternal and embryonic genotypes are involved in determining NTD risk. However, most of the reported associations have been weak and have not been consistently replicated (239).

Three studies have undertaken more comprehensive evaluations of the association between NTDs and variants of folate-related genes (124,240,241). These studies differed both in the genes/SNPs that were included as well as the number of SNPs evaluated per gene, including between 46 and 118 SNPs in 11–45 genes. However, in two studies there was evidence for associations between NTDs and variants of CBS, DHFR, MTHFR and TYMS (Shaw, Martinez), which adds to the evidence suggesting that these genes are involved in the etiology of NTDs. Moreover, the study by Franke et al. implicated CUBN as a potential NTD risk factor and provided some evidence for an association of NTDs with SLC19A1, which has been implicated as an NTD risk factor in other studies (242).

Other groups of candidate genes have also been considered as potential risk factors for NTDs. Candidate

genes have been selected based on known risk factors for NTDs; for example, genes that predispose to the development of maternal conditions (e.g. diabetes, obesity) that are associated with an increased risk of NTDs (48,243), genes that are critical during embryogenesis (e.g. DNA repair genes) (244,245), genes involved in the metabolism of known teratogens (e.g. valproic acid), and genes involved in the metabolism of compounds (e.g. cholesterol) that are required for embryonic development (246). The human orthologs of genes, which when mutated or knocked out in the mouse are associated with NTDs, are also good candidate genes for NTDs in humans (247,248). Although candidate gene studies of non-folate-related candidate genes also have not identified any genes or genetic variants that are consistently associated with NTD risk, none of the genes that have been evaluated as NTD risk factors (including the folate-related candidate genes) have been studied in sufficient detail to warrant their exclusion as candidates.

In addition to candidate gene association studies, a genome-wide linkage analysis of NTDs has been completed (21). Through a collaborative effort, 44 families with two or more individuals affected with a defect of the neural tube were assembled for the purpose of a genome-wide linkage analysis. Owing to the rarity of such families, affected individuals had a broad spectrum of conditions including anencephaly, myelomeningocele, lipomyelomeningocele, encephalocele, and craniorachischisis. When a narrow phenotypic definition was applied (i.e. lumbosacral myelomeningocele), the sample was reduced to 17 families. A microsatellite-based genome screen in these families identified regions of interest on chromosomes 7 (attributable to a single large pedigree) and 10. The results of these analyses provide positional data for the prioritization of candidate genes in future studies.

The relative lack of success in identifying genetic variants that are related to the risk of NTDs in humans is somewhat surprising given the large number of mouse models that provide strong evidence of the genetic contribution of NTD. To date, over 240 gene mutations have been associated with NTD in mouse lines (47), yet none of the 155 genes implicated by these models has been identified as a determinant of NTD risk in humans. In general, the lack of success in past studies in humans is likely to reflect a number of factors including issues of sample size and power, etiologic heterogeneity and failure to adequately capture the etiological complexities that are likely to underlie human NTDs. These complexities are likely to include gene-gene and gene-environment interactions, maternal and the embryonic genotypic effects, the involvement of both rare and common variants, and consideration of pathways (as opposed to individual genes).

As an example of the need to consider pathways and rare variants, consider the following grouping of genes, which is suggested by mouse models of NTDs: Cobl, Vangl, Celsr, Scrb, Ptk7, Fuz, Fzd, and Dvl. These genes

are mechanistically connected through the planar cell polarity pathway (PCP) of noncanonical Wnt signaling and include both receptors and downstream effector molecules that play critical roles in determining cell shape and position during neural tube closure (248). In mouse embryos, defective PCP genes are associated with abnormal convergent extension (14,84,249). In humans, sequencing of PCP genes has led to the identification of rare mutations in *VANGL* and *VANGL1* in individuals with NTDs (250–252). These findings demonstrate that DNA resequencing of a reasonable number of subjects can identify important novel SNPs that are highly relevant to disease risk and that the interrogation of all variants in the protein coding regions of candidate genes in order to establish a clinically useful panel of predictive markers is important.

### 114.5 DIAGNOSIS, TREATMENT, AND OUTCOME

Screening to identify pregnant women who are at an increased risk of carrying an NTD-affected fetus can be achieved by the evaluation of maternal serum alpha-fetoprotein levels and/or ultrasound imaging (253–255). Follow-up studies for women with a positive result on either screening test include amniocentesis and/or detailed ultrasound evaluation. When amniocentesis is performed, evaluation of amniotic fluid alpha-fetoprotein and acetylcholinesterase levels can be used to confirm the presence of an open fetal malformation and differentiate between open ventral wall and open NTDs. In addition, the fetal karyotype can be evaluated to rule out chromosomal anomalies. Detailed ultrasound can also be used to differentiate between open defects of the ventral wall and neural tube, and to identify the presence of other associated anomalies (256). When a diagnosis of spina bifida is confirmed, ultrasound and prenatal magnetic resonance imaging (using ultrafast T2-weighted sequences) can be used to identify spontaneous leg and foot motion, leg and spine deformities, and the presence of a Chiari II malformation (257).

Although anencephaly and craniorachischisis are lethal conditions, individuals with spina bifida can survive with appropriate medical treatment. Mode of delivery (cesarean vs vaginal) does not appear to influence the outcome of children with spina bifida (258). However, cesarean section may be appropriate for infants with large spina bifida lesions, to reduce the risk of trauma (258), and is performed following in utero treatment of spina bifida because of the risk of dehiscence during labor.

The majority of individuals with spina bifida have their spinal lesion closed postnatally, usually within 72 h of birth (180,259). However, a small proportion of fetuses have had their lesion closed in utero. A randomized clinical trial designed to compare the outcome of infants treated postnatally with those treated in utero was initiated in 2003 and stopped in December 2010 based on

the evidence for efficacy of prenatal surgery (260). Based on data from 158 patients who underwent a 12-month evaluation, the primary outcome (death or need for cerebrospinal fluid shunt by 12 months) was significantly less common in infants undergoing prenatal as compared to postnatal surgery (relative risk 0.70; 97.7% CI 0.58, 0.84). The prenatal surgery group also had lower rates of hindbrain herniation, brain-stem kinking and syringomyelia and, at 30 months, the difference between the functional and anatomical level of the lesion was significantly better as compared to the postnatal surgery group.

Whether treated in utero or postnatally, individuals with spina bifida are at risk for associated malformations of the nervous system including hydrocephalus and Chiari II malformations. Lower extremity weakness and paralysis, sensory loss, and bowel and bladder dysfunction are also common. The most important determinant of neurological function is the upper level of the spinal lesion. Individuals with spina bifida are also at risk for a range of orthopedic abnormalities including clubfoot, contractures, hip dislocation, scoliosis, and kyphosis. Moreover, while most individuals with spina bifida have normal intelligence, specific cognitive and language difficulties are common (261). Given the range of physical and developmental problems associated with spina bifida, the care of individuals with this condition is best provided by a multidisciplinary team (259).

The most recent population-based data indicate that among individuals with spina bifida 1-year survival is approximately 87%, and approximately 78% survive to the age of 17 years (262). Among survivors there is significant morbidity. In a cohort of 54 adults with spina bifida (mean age 35 years), all of whom had their lesion closed with 48 h of birth, only 30% could walk at least 50 m without aid, 41% lived independently, 54% had passed a driving test, and 24% were in open employment. Relatively little is known about the specific health problems encountered by adults with spina bifida. However, it appears that excess morbidity and mortality do continue throughout the adult years (259,263). In a cohort of 117 individuals with spina bifida who were born in the United Kingdom between 1963 and 1971, the mortality rate from age 5–40 years was 10 times that of the national average. Approximately 50% (16/31) of the deaths that occurred in this age group were considered to be unexpected. The most common causes of unexpected death were epileptic seizure, pulmonary embolism, renal sepsis and acute hydrocephalus ( $N = 3$  each) (264).

### 114.6 PREVENTION

Like many other birth defects and genetic disorders, NTDs can be identified in the prenatal period and are, therefore, amenable to secondary prevention through elective termination of affected pregnancies. However, NTDs stand as one of the few birth defects for which primary prevention strategies are also available. Research

spanning several decades, including randomized (265) and community-based (266) clinical trials demonstrate that maternal periconceptional supplementation with folic acid alone, or multivitamins containing folic acid can reduce the risk of NTDs in offspring by 50–70%.

Numerous studies have demonstrated that women who take a daily folic-acid-containing supplement are at significantly reduced risk of having a child with an NTD, compared with women who do not take such supplements (204,265,267). Consequently, health agencies in several countries have established policies concerning the use of folic acid supplements to prevent NTDs (268,269). However, translating such policies into practice has proven to be extremely difficult. Despite numerous public health campaigns, a substantial proportion of reproductive age women are unaware of, or do not follow, recommendations regarding the need to take folic acid before and during pregnancy for the prevention of NTDs (270–276). Moreover, such policies do not appear to reduce the prevalence of NTDs at the population level (277,278).

Because of the difficulties inherent to public health efforts aimed at widespread changes in behavior, several countries have initiated mandatory folic acid food fortification programs. Cordero et al. (157) noted that 53 countries have established regulations for mandatory fortification of wheat flour with folic acid. Once implemented, such fortification programs can reduce the prevalence of NTDs by approximately 50% (40) and are associated with significant cost savings (110,279). Unfortunately, since folic acid fortification has not been universally implemented and those programs that have been implemented may not be fortifying at optimal levels, it is estimated that only 9% of the folate-preventable NTDs are currently being prevented (280). Indeed, the US Preventive Services Task Force has reiterated that “All women capable of pregnancy should take a daily vitamin supplement that contains 0.4–0.8 mg of folic acid” and noted that “It is not known whether women can get enough folic acid to prevent NTDs simply by eating folic acid-fortified foods” (281).

### 114.7 GENETIC COUNSELING

NTDs can be divided into those that are associated with a chromosomal abnormality, single gene disorder, or teratogenic exposure, and those for which a single causative agent cannot be identified. Therefore, accurate genetic counseling for affected individuals and their relatives requires a thorough evaluation of the underlying cause of NTDs in all affected family members. This includes evaluation of family, medical, and reproductive histories and, when possible, karyotype analysis and clinical or postmortem examination of the affected family members (41).

When an underlying cause of an NTD is identified (e.g. chromosomal aneuploidy, maternal diabetes), recurrence

risk counseling and guidance regarding prenatal care, screening, and testing should be tailored to the specific underlying cause. However, it is unclear whether NTDs that occur in association with an underlying condition or exposure are solely the result of that condition or whether the underlying condition or exposure increases the vulnerability (i.e. shifts the threshold) of the embryo to the development of an NTD (282). If the latter is true, then families that have had a child with an NTD that occurred in association with an underlying condition or exposure may be at increased risk (relative to the general population) of having a child with a nonsyndromic NTD (283).

Although NTDs can occur as part of chromosomal or single gene disorders or as a result of teratogenic exposures, a specific causative agent cannot be identified for the majority of affected individuals. NTDs that cannot be linked to a specific cause are thought to result from the cumulative effects of multiple genetic/environmental risk factors. Recurrence risk counseling for this group of NTDs is based on empirical risk estimates. In general, the recurrence risk for a sibling of an affected individual is reported to be 3–5%. Increased risks (relative to the general population) are also generally reported for second-degree and third-degree relatives, but these risks are less precisely defined than those for siblings. It is of note that the vast majority of studies that assessed recurrence risks for NTDs were conducted before the 1990s and the widespread recognition of the NTD protective effect of folic acid. Hence, it is unclear to what extent these estimates apply at the present time.

In the United States and many other areas of the world, it is recommended that all women of childbearing age consume a daily multivitamin supplement containing at least 0.4 mg of folic acid in order to reduce their risk of having a child with an NTD. Women who have had a child affected with an NTD may be counseled to take higher doses of folic acid as per the initial recommendations from the Centers for Disease Control (232). Specific recommendations for other categories of high-risk women (e.g. sisters of women who have had an affected pregnancy, women who take antiepileptic drugs such as valproic acid, and diabetics) are not available.

As folic acid supplementation does not prevent 100% of all NTDs, women who are at increased risk for having an affected child (whether or not they are taking folic acid supplements) should be informed of the availability of MSAFP screening/ultrasound/amniocentesis for the prenatal identification of affected fetuses. At this time, there are no recommended genetic screening or testing procedures for nonsyndromic NTDs. Evaluation of genetic variants such as the MTHFR C677T polymorphism, is not currently recommended because of the lack of consistent associations across studies, the relatively low proportion of cases that are likely to be attributable to any single genetic factor, and the fact that it would not change preconceptional advice regarding the utility of vitamin supplements or pregnancy management (284).

## ACKNOWLEDGMENTS

Dr Finnell and a portion of the work provided in this chapter were supported in part by grants DE13615, NS050249, and HD058912, from the National Institutes of Health, RD-83428901 from the US Environmental Protection Agency, and from the Centers of Disease Control and Prevention, Centers of Excellence Award No. U01/DD000491, U01/DD000493, U01/DD000494. Dr Mitchell and a portion of the work provided in this chapter were supported in part by grants HD39195 from the National Institutes of Health and U01/DD000494 from the Centers for Disease Control and Prevention.

### Biographies

**Richard H Finnell** is a Professor in the Department of Nutritional Sciences and the Department of Chemistry and Biochemistry at the University of Texas at Austin and serves as the Director of Genomic Research at Dell Children's Medical Center. A pediatric geneticist, he has a distinguished career researching environmentally induced birth defects. Dr Finnell serves on the National Advisory Environmental Health Sciences Council and is a member of the CICbio-GUNE Research Institute Scientific Advisory Board in Bilbao, Spain, where he also holds a research appointment. Research at the Finnell Laboratory focuses on the interaction between specific genes and nutritional factors as they influence normal embryonic development and susceptibility to complex birth defects.

**Laura E Mitchell** is a Professor in the Division of Epidemiology, Human Genetics and Environmental Sciences at the University of Texas School of Public Health in Houston. She is a genetic epidemiologist with expertise in the design and analysis of population and family-based studies of common structural birth defects. Research in her group focuses on the identification and characterization of genes that influence disease risk and includes an emphasis on methods for identifying maternal genetic effects that influence the risk of birth defects in offspring.

**Timothy M George** is the Chief of Pediatric Neurosurgery and Neurosciences at the Dell Children's Medical Center in Austin. Additionally, he is an Adjunct Professor of Cell and Molecular Biology at The University of Texas at Austin and serves as Director of the Pediatric Educational and Translational Research Institute. Dr George serves on Biomedical Engineering Advisory Board and the McCombs Business School Health Care Initiative Advisory Board at The University of Texas at Austin. His research focuses on the molecular genetics of neural tube defects.

**115.1 INTRODUCTION**

The widespread clinical use of MRI, with its ability to image the human brain noninvasively, has revolutionized our understanding of cerebral cortical malformations. Although some dramatic cortical malformations can be associated with remarkably preserved intellect, most brain malformations cause severe neurological disability. Genetic disorders of cortical development include sporadic noninherited anomalies, as well as a growing variety of malformations with distinct inheritance patterns. Consequently, accurate diagnosis and genetic counseling requires precise definition of the anatomical abnormalities and the clinical spectrum of each disorder. Since malformations of the cerebral cortex have their origins during the dynamic process of cortical development, understanding normal cortical development is essential when considering these disorders. Therefore, the process of normal development of the human cerebral cortex will be reviewed briefly before discussing individual cortical malformations.

The neurons of the cerebral cortex are formed in a pseudostratified columnar neuroepithelium of the ventricular zone and then migrate over considerable distances to reach their final destination in the cortex. Neural progenitor cells in the ventricular zone are called radial glia cells (1). They give rise to postmitotic neurons, which migrate toward the surface, and also to a secondary population of progenitor cells in the subventricular zone (the region immediately superficial to the ventricular zone) (2). The

subventricular zone contains two major types of progenitors. Basal progenitors appear to be short-lived intermediate progenitors that produce individual cell types such as neuron or glia (2–5). In addition, a recently described population of multipotential progenitors with radial glia-like morphology in the outer subventricular zone is especially common in the brains of humans and other mammals with a large cerebral cortex (6–8).

The first group of postmitotic neurons produces a pioneer layer called the primordial plexiform layer (9,10). This layer, also called the “preplate” is later split into an outer layer (“marginal zone”) and a deeper layer (“subplate”) by the later-arriving neurons that form the cortical plate. Neurons add to the cortical plate in an inside out manner, so that newer-arriving neurons always migrate past the older cortical plate neurons until they arrest next to the marginal zone (11,12). The marginal zone, which contains specialized neurons called Cajal-Retzius cells, seems to be instrumental in establishing the inside out laminar gradient of the cortical plate. In the human cortex, postmitotic neurons start to migrate out of the ventricular zone between the sixth and seventh week of gestation to form the primordial plexiform layer (10,13). Migration of neurons appears to peak between the 11th and 15th week of gestation (11). Although it is not entirely clear when migration is finally completed in the cerebral cortex, the majority of neurons have entered the cortex by around the 24th week of gestation (10,14).

The migration of cortical plate neurons is guided by long radially aligned fibers of radial glial cells (12,15,16). The outermost processes of these radial glial cells form the outer limiting membrane of the brain, consisting of glial endfeet apposed to a basement membrane contributed both by neural and extra-central nervous system (CNS) cells [reviewed in (17)]. Nonradial (tangential) neuronal migration is also common in the developing cortex (18), with a large fraction of cerebral cortical neurons, particularly inhibitory interneurons, originating outside of the cortex itself, in other brain regions that give rise to the basal ganglia (19–21). A vast diversity of molecules has been implicated in the development of the cortex through animal studies but will be reviewed here only if they specifically relate to known human genetic disorders.

Although a standard and universally applied classification scheme for malformations of cortical development is yet to be developed, a system proposed by Barkovich et al. (22,23) serves as a useful framework (Table 115-1). The Barkovich et al. scheme is primarily organized according to a triad of embryology, genetics, and neuroimaging. Our presentation of cortical disorders will generally follow this outline.

## 115.2 MALFORMATIONS DUE TO ABNORMAL NEURONAL AND GLIAL PROLIFERATION OR APOPTOSIS

### 115.2.1 Microcephaly: An Overview

Microcephaly is a condition in which the cranial vault, defined by the occipitofrontal head circumference (OFC), is significantly smaller than expected for an individual's age and sex (>2 standard deviations smaller than the mean; or more conservatively, >3 standard deviations) (24,25). The etiology of microcephaly is extremely diverse, posing significant challenges to clinicians dealing with this condition, but can be broadly divided into environmental and genetic causes (26). Common environmental causes include congenital infection, intrauterine exposure to teratogenic agents, and hypoxic-ischemic injury. The clinical history usually provides important diagnostic clues in these cases. On the other hand, genetic causes of microcephaly are also quite diverse. Inherited metabolic disorders usually cause postnatal onset of microcephaly (acquired microcephaly) and are not discussed here.

Genetic causes of microcephaly that are associated with the presence of microcephaly at birth (congenital microcephaly) usually represent developmental malformations of the cerebral cortex. For example, microcephaly is frequently seen in association with a variety of chromosomal abnormalities and other well-defined genetic syndromes (e.g. Smith-Lemli-Opitz syndrome; OMIM 270400) that are discussed elsewhere in this book. In these cases, the characteristic patterns of involvement of other organ systems and/or the presence

of specific dysmorphic features often help make the diagnosis. Other well-characterized CNS disorders such as neuronal migration disorders (e.g. lissencephaly) can be associated with microcephaly without other organ involvement, and these conditions are described later in the chapter. Finally, there are an increasing number of syndromes and genetic loci (e.g. microcephaly vera) in which the CNS is typically the only affected organ system and in which the brain is characteristically quite small. These disorders are discussed below.

**TABLE 115-1 Classification of Cortical Malformations**

I. Malformations due to abnormal neuronal and glial proliferation or apoptosis
A. Decrease proliferation/increased apoptosis (microcephaly)
1. Microcephaly with normal or mildly simplified gyri
a. Microcephaly vera (primary autosomal recessive microcephaly)
b. Microcephaly, seizures and developmental delay (early infantile epileptic encephalopathy 10)
c. Microcephaly with proportionate short stature
d. Others
2. Microlissencephaly (severe microcephaly with significant simplification of gyri)
3. Microcephaly with other brain malformations (e.g. polymicrogyria, pontocerebellar hypoplasia)
B. Increased proliferation/decreased apoptosis (megalencephaly)
C. Abnormal proliferation and differentiation (nonneoplastic)
1. Cortical tubers of tuberous sclerosis
2. Focal cortical dysplasia
3. Hemimegalencephaly
II. Malformations due to abnormal neuronal migration
A. Classical lissencephaly/subcortical band heterotopia
1. LIS1-associated lissencephaly
2. X-linked lissencephaly 1
3. X-linked lissencephaly 2
4. TUBA1A-associated lissencephaly
B. Cobblestone dysplasia
C. Gray matter heterotopia
1. X-linked periventricular heterotopia
2. Autosomal recessive periventricular heterotopia with microcephaly
3. Heterotopia due to chromosomal aberration
III. Malformations due to abnormal cortical organization (including later stages of neuronal migration)
A. Polymicrogyria
1. Bilateral frontoparietal polymicrogyria
2. Bilateral perisylvian polymicrogyria
3. Bilateral occipital polymicrogyria
4. Bilateral generalized polymicrogyria
5. Other localized polymicrogyria syndromes
6. Tubulin-associated polymicrogyria
7. Polymicrogyria due to chromosomal aberration
B. Schizencephaly
IV. Malformations of cortical development, not otherwise classified
A. Malformations secondary to inborn errors of metabolism
B. Others

Modified from (22,23).

### 115.2.2 Microcephaly Vera

This term, meaning “true” microcephaly, was coined by Giacomini in 1885 to denote a condition in which no gross pathological abnormality other than the small size of the brain was observed (27). Clinically, this term has been used to describe a group of patients characterized by the presence of microcephaly at birth, relatively normal early motor milestones, and intellectual disability of variable severity. Microcephaly is usually profound, ranging between  $-4$  and  $-12$  standard deviations below the mean for the age (28,29). Usually there are few dysmorphic features other than those that arise as a consequence of the microcephaly, including a narrow sloping forehead and relative prominence of ears. Seizures are relatively uncommon in this group of patients, although reported in some cases (30). When early-onset seizures are a prominent feature but the rest of clinical characteristics resemble microcephaly vera, patients may fall into the category of the recently characterized syndrome of microcephaly, seizures, and developmental delay (see below).

**115.2.2.1 Genetics and Biology.** Microcephaly vera is inherited as an autosomal recessive trait, and it is genetically highly heterogeneous. To date, seven genes in seven loci (termed MCPH1 through 7) have been identified to be associated with microcephaly vera: *MCPH1* (also known as *microcephalin*; the MCPH1 locus; OMIM 251200) (31), *WDR62* (MCPH2; OMIM 604317) (32–34), *CDK5RAP2* (MCPH3; OMIM 604804) (35), *CEP152* (MCPH4; OMIM 604321) (36), *ASPM* (MCPH5; OMIM 608716) (37), *CENPJ* (MCPH6; OMIM 608393) (35) and *STIL* (MCPH7; OMIM 612703) (38). Among these genes, *ASPM* mutations appear to be the most common and may account for approximately 40% of patients who fit the clinical description of microcephaly vera (39,40).

Upon brain MRI, patients with microcephaly vera typically show a normal or mildly simplified gyral pattern. Cortical thickness appears normal. In patients with *ASPM* mutations, associated abnormalities such as agenesis of corpus callosum, enlarged lateral ventricles (particularly of the occipital horn), and focal cortical malformations (e.g. unilateral polymicrogyria or focal cortical dysplasia) are sometimes seen (41). *WDR62* mutations are associated with the more frequent presence of associated structural abnormalities, which include severe simplification of gyri, polymicrogyria hypoplasia or partial agenesis of the corpus callosum and schizencephaly (32–34). Missense *WDR62* mutations appear to be associated with less severe structural abnormalities compared to truncating mutations (33).

The proteins encoded by the genes associated with microcephaly vera localize, at least in part, to the mitotic centrosomes and are involved in the regulation of cell cycle and cell division during early cortical development (28). Thus these proteins are thought to regulate

proliferation of neural progenitor cells in the developing cerebral cortex. Although the exact mechanisms by which these proteins regulate cell cycle and cell division are not entirely clear, *ASPM* has been shown to maintain symmetrical cell division (in which neural progenitors generate two progenitors as daughter cells, as opposed to generating one progenitor and one postmitotic neuron) (42). This function likely prevents premature depletion of neural progenitors. *MCPH1* contains three BRCT (BRCA1 C-terminal) domains. Many proteins with this domain are known to function in DNA repair, and *MCPH1* has also been implicated in DNA damage response (43). In addition, it is implicated in chromosome condensation during mitosis (44) and chromatin remodeling (45).

Patients with congenital microcephaly who also have intractable seizures starting during infancy have been found to have recessive mutations in the DNA repair protein gene *PNKP* (46). This entity is variably called microcephaly, seizures, and developmental delay or early infantile epileptic encephalopathy 10 (OMIM 613402). These patients typically show head circumference of  $-2$  to  $-3$  SD at birth and  $-4$  to  $-7$  SD during childhood and have severe intellectual disability. However, milder mutations lead to milder microcephaly ( $-2$  to  $-3$  SD below the mean during childhood) and less severe seizures and intellectual disability. Unlike other disorders that affect DNA repair (e.g. ataxia telangiectasia), microcephaly due to mutations in *PNKP* has not been associated with immunodeficiency or cancer, although no long-term follow-up is available for patients with *PNKP* mutations.

Patients with microcephaly vera have severe microcephaly, but their linear growth is much less affected. On the other hand, there are patients with severe congenital microcephaly with proportionate growth retardation. Clinical entities associated with this type of presentation include Seckel syndrome (OMIM 210600 for the *SCKL1* locus) and microcephalic osteodysplastic primordial dwarfism types I (MOPD I; OMIM 210710) and II (MOPD II; OMIM 210720). Some patients with Seckel syndrome have been found to have recessive mutations in *ATR* (47), which is closely related functionally to *ATM*, the gene mutated in ataxia telangiectasia, and is also involved in DNA damage response (48). Recessive mutations in one of the genes associated with microcephaly vera, *CEP152*, have also been found in patients with a diagnosis of Seckel syndrome (49), suggesting overlap between these two conditions. MOPD II has been associated with recessive mutations in *PCNT2*, whose protein product localizes to centrosome (50,51) but may also be involved in DNA damage response like *ATR* and *MCPH1* (50). Thus these microcephaly syndromes with short stature and microcephaly vera may represent defects in overlapping biological pathways.

An autosomal dominant form of microcephaly (OMIM 156580) has been described and is perhaps

relatively common among individuals with mild ( $-2$  to  $-3$  SD) microcephaly, but little is known about its cause. This form of microcephaly is often associated with normal intelligence and may not come to clinicians' attention very often (52). The assessment of recurrence risk of microcephaly is therefore often challenging because of the heterogeneous nature of this condition. Unless the mode of inheritance is evident from family history, examination and laboratory investigations, accurate assessment may be difficult. In one population-based study in British Columbia, Canada, the recurrence risk of intellectual disability in the siblings of microcephalic individuals was estimated to be 5.9%, one-third of whom also had microcephaly (53). Another study estimated the recurrence risk of microcephaly in siblings of microcephalic individuals to be 19% (54), more suggestive of an autosomal recessive trait. This large difference may be due to differences in the percentage of autosomal recessive forms of microcephaly in each population studied.

In patients with microcephaly vera, the gyral pattern is relatively well preserved despite the often strikingly small size of the brain (Figure 115-1). Pathological studies of the brain are few, but they thus far reveal no microscopic abnormality in cortical laminar formation (55,56). In some cases, a reduced number of neurons in cortical layers II and III, which are superficial layers (57), or neuronal heterotopias (55) have been observed. Although a decreased number of neurons in the cerebral cortex is considered to be primarily responsible for the small size of the brain in microcephaly vera, there are many potential ways in which the number of cortical neurons can be subnormal. For example, decreased proliferation of neuronal progenitors, decreased production of mature neurons by each neuronal progenitor, or excessive cell death of neuronal progenitors or of mature neurons all lead to decreased numbers of neurons in animal models (58,59).

### 115.2.3 Microlissencephaly

It has been long known that some patients with congenital microcephaly present with more severe neurological signs, such as spasticity, severe developmental delay, and seizures. Some of those patients have striking simplification of cortical gyral pattern (more significant than what is seen in patients with microcephaly vera), and the term microlissencephaly (microcephaly + lissencephaly) may be applied to those cases (60–62). This is clearly a highly heterogeneous group. Survival varies significantly, with some patients dying within days or weeks (63) but others living for years. Associated neuroimaging findings may include pontocerebellar hypoplasia, enlarged extra-axial spaces, and polymicrogyria (64). This clinical and radiological variability may reflect their distinct pathogeneses.

**115.2.3.1 Genetics and Biology.** Recently, recessive mutations in the *NDE1* gene were identified in patients with severe congenital microcephaly, severe simplification of gyral pattern, and the variable presence of spasticity and seizures (65,66). The homolog of NDE1 in *Aspergillus nidulans*, NudE, is an essential regulator of nuclear migration pathway (thus the name Nuclear distribution E) and interacts with the homologs of LIS1 (whose mutations are associated with classical lissencephaly discussed below) (67). This interaction is also preserved in mammals (58,68,69). In addition, similar to other genes associated with microcephaly vera, NDE1 localizes to the mitotic centrosome, and its defects lead to failure in mitotic progression (65,66). Thus, the clinical characteristics of severe microcephaly associated with lissencephaly may be explained by the essential roles of NDE1 in both neurogenesis and neuronal migration. The genetic basis of other types of microlissencephaly has not been elucidated.

**FIGURE 115-1** T2-weighted axial MRI images of a normal 4-year-old girl (A) and a 3-year-old girl with microcephaly vera (B) are shown. The gyral pattern is mildly simplified in the patient, but there are no other structural abnormalities, except for the striking smallness of the brain. The patient was found to have a mutation of the *ASPM* gene. Scale bar = 2 cm.

### 115.2.4 Other Microcephaly Syndromes

Several other novel microcephaly syndromes have emerged in recent years. Intellectual disability and variable postnatal microcephaly (ranging from normal to almost –6 SD below mean; MRT13; OMIM 613192) has been associated with mutations in *TRAPPC9* (70–72). Brain MRI of these patients may reveal paucity and signal abnormalities of the cerebral white matter (70–72). The *CASK* gene on the X chromosome was found to be mutated in patients with congenital or postnatal microcephaly with disproportionate brainstem and cerebellar hypoplasia (OMIM 300749) (73).

### 115.2.5 Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC; OMIM 191100 for *TSC1* and 613254 for *TSC2*) is an autosomal dominant multiorgan disorder that commonly affects the brain, eyes, skin, kidneys and heart. TSC is discussed in this section as its fundamental defects include cell proliferation, fate determination and differentiation. Neurological manifestations, which are usually the major clinical problems, include epilepsy, intellectual disability and autistic symptoms. In the brain, the characteristic lesions of TSC are cortical tubers, subependymal nodules, and subependymal giant cell astrocytomas (SEGAs). Cortical tubers are circumscribed areas of dysplastic cortex, which appear pale and have firmer consistency compared to the normal cortex (74). Within the tubers, the normal laminar structure is lost and enlarged dysmorphic neurons as well as “giant cells” (or “balloon cells”) with abundant eosinophilic cytoplasm are seen. These giant cells variably express neuronal and glial markers (75). In TSC, subependymal nodules project into the third and lateral ventricles as smooth firm nodules, forming classic “candle gutterings” (74). They may continue to grow and form SEGAs, but the molecular mechanisms of this transformation remain to be understood. Many of the histological features that are observed in cortical tubers are also seen in subependymal nodules and SEGAs, but the cellular packing density of these latter lesions is much higher than that of cortical tubers.

**115.2.5.1 Genetics and Biology.** TSC is caused by mutations in one of the two genes, *TSC1* and *TSC2*. In *de novo* cases, *TSC2* mutations have been found 2–10 times more often than *TSC1* mutations (76–81). However, about half of the familial cases are due to mutations in *TSC1* and the rest are due to mutations in *TSC2* (81,82). *TSC2* mutations are associated with a higher frequency of cystlike tubers, which may predispose to a more aggressive seizure phenotype (83). The *TSC2* gene in chromosome 16p13 encodes a protein called tuberin, which encodes a GTPase activating protein (GAP)-related domain (84). Tuberin has been shown to have GAP activity for Rap1 and Rab5 (85,86). The *TSC1* gene in chromosome 9q34 encodes a protein named hamartin (87).

Tuberin and hamartin interact directly (88–90) and act as critical negative regulators of the mTOR (mammalian target of rapamycin) signaling pathway, an important pathway regulating cell growth in response to growth factors and other metabolic stimuli (91–93). Thus TSC lesions show abnormal mTOR activation, with enlarged and dysplastic-appearing cells.

The focal nature of TSC lesions appears to be explained by the “two-hit” hypothesis, originally developed by Knudson for the retinoblastoma gene (94). In the “two-hit” model, all somatic cells harbor a mutation in one allele, and a subsequent random “second hit” or spontaneous mutation in the other “healthy” allele is required for a dividing cell and the daughter cell of that cell to develop an abnormal phenotype. This hypothesis is supported by the fact that loss of heterozygosity (which indicates that the second hit has occurred) for *TSC1* or *TSC2* locus has been detected in some TSC lesions (95,96). In CNS lesions, loss of heterozygosity has been demonstrated to occur rarely if at all (97,98); whether this reflects a pathogenesis of CNS lesions different from other TSC lesions is unclear.

The central involvement of the mTOR pathway in the pathogenesis of TSC has led to the hypothesis that some manifestations of TSC may be amenable to treatment with rapamycin and its derivatives (99–102). The role of rapamycin vs neurosurgical intervention for the treatment of SEGAs is still to be determined at the time of the writing of this chapter (103), and clinical trials to evaluate the effects of rapamycin on neurocognitive outcomes in children with TSC are still in progress. TSC is an exemplar of a neurodevelopmental condition with potential disease-specific treatments that may follow from the study of the genetics of the disorder.

### 115.2.6 Focal Cortical Dysplasia

Focal cortical dysplasias (FCDs; OMIM 607341) are dysplastic zones of cortex, usually occurring as solitary lesions that interrupt the otherwise morphologically normal cortex. FCDs share some radiographic and histological similarities with the cortical tubers of TSC (104–106). Histologically, FCDs contain large bizarre neurons in all but the first cortical molecular layer, with a loss of cortical lamination. Grotesque, glia-like cells are present in the depth of the affected cortical region and in the underlying demyelinated white matter (105). “Balloon cells” with glassy eosinophilic cytoplasm and pleomorphic eccentric nuclei have been demonstrated in cases of FCD (105) and were found to express neuronal markers, glial markers, or both (107,108). FCD is a well-known cause of intractable epilepsy (109,110), but it is sometimes not identified in the initial MRI scan unless there is a high degree of suspicion for a focal abnormality at a specific location; appropriate signal sequences and reconstructions may need to be performed to optimize detection of small or relatively subtle FCD.

The most common MRI picture of FCD takes the form of a thickened bumpy cortex with shallow and wide sulci. Deep infoldings of thickened cortex may also be found (104).

The neuropathological findings of FCD, which are the basis of the classification of FCD into subtypes (110), have led to the hypothesis that FCDs may represent focal somatic mutations that have occurred early in cortical development, perhaps in the *TSC* genes or in related genes, but this has not been definitively demonstrated. The histological features of FCD are strikingly similar to that of TSC, and it has been debated whether sporadic FCD, in the absence of the other stigmata of TSC, represents a “forme fruste” of TS (111). Studies have shown different patterns of gene expression in these two disorders, and this may suggest distinct pathogenetic mechanisms at work (112,113). On the other hand, loss of heterozygosity at the *TSC1* locus has been identified in some of microdissected tissue samples of FCD, possibly suggesting a pathogenetic relationship (114,115).

FCD usually occurs in a sporadic, noninherited form. A pedigree was reported several years ago with apparent familial cortical malformations including FCD among other malformations; on careful inspection images from an affected individual with FCD appear more typical of asymmetric perisylvian polymicrogyria than the typical FCD (116). More recently, there has been one demonstration of a genetic etiology for focal cortical dysplasia in an Amish pedigree with an autosomal recessive mutation in the gene *CNTNAP2*; the affected individuals had medically intractable focal epilepsy, intellectual disability, and aggressive behavior (117). *CNTNAP2* has also been reported to be associated with autism (118–121) and Pitt-Hopkins-like syndrome 1 (OMIM 610042) (122).

### 115.2.7 Hemimegalencephaly

Hemimegalencephaly is characterized by unilateral enlargement of only one cerebral hemisphere. The entire cerebral hemisphere may be enlarged, but sometimes only half or part of the affected hemisphere is involved. The enlarged hemisphere usually shows gyral abnormalities in the form of agyria/pachygyria or polymicrogyria, and the lateral ventricle on the abnormal side is often enlarged (123). Boundaries of gray and white matter may be blurred, and gray matter heterotopia may be found. Microscopically, cortical laminar disorganization, neuronal cytomegaly, and heterotopic neurons in the white matter are seen (124,125). The diagnostic criteria for hemimegalencephaly are not precise, so the term is often applied to virtually any cortical malformation that involves most of a single hemisphere.

A typical clinical presentation includes contralateral hemiparesis, epilepsy, and intellectual disability (123). Seizures often start during the first days of life and are typically intractable to medical management. In fact, early resistance to antiepileptic drugs is common (126). Partial seizures with or without secondary

generalization and infantile spasms are common (127,128). Hemispherectomy can be an effective treatment for seizure control (126). Cognitive development may vary widely. Patients with normal intellectual development have been reported (129), but this is uncommon.

Hemimegalencephaly can be seen as an isolated malformation or in association with various neurocutaneous syndromes such as hypomelanosis of Ito (OMIM 300337) (130,131), Shimmelpenning-Feuerstein-Mims syndrome (also known as linear sebaceous nevus syndrome or epidermal nevus syndrome; OMIM163200) (132,133), Proteus syndrome (OMIM 176920) (134), and Klippel-Trénaunay-Weber syndrome (OMIM 149000) (135). In addition, rare association with neurofibromatosis type I (OMIM 162200) (136) and TSC (OMIM 19100 and 613254) (137) have been reported. Thus, a careful skin examination is mandatory in patients with this condition. Hemimegalencephaly is typically encountered as a sporadic, noninherited condition. Therefore, the risk of recurrence is considered small when there is no association with a known inherited syndrome.

Histological characteristics, such as neuronal cytomegaly and heterotopic neurons, closely resemble TSC and FCD. In some cases, “balloon cells” similar to those seen in TSC and FCD are also observed. In contrast, a comparison between “balloon cells” seen in hemimegalencephaly vs TSC has shown different immunohistochemical and ultrastructural characteristics of the abnormal neurons in each condition (138). It is conceivable that somatic mosaicism may play a role in the pathogenesis of hemimegalencephaly, but definitive evidence is lacking.

## 115.3 MALFORMATIONS DUE TO ABNORMAL NEURONAL MIGRATION

### 115.3.1 Classical Lissencephaly: An Overview

Lissencephaly represents a smooth brain with a lack or severe paucity of normal gyri. Classical (or Type I) lissencephaly is characterized by a severely thickened cerebral cortex with three or four abnormal layers instead of the normal six cortical layers. On the other hand, “cobblestone” (or Type II) lissencephaly is a completely different entity histologically (see Section 115.3.7). Several clinical entities are associated with classical lissencephaly, including isolated lissencephaly sequence (ILS), Miller-Dieker syndrome (MDS; OMIM 247200), X-linked lissencephaly 1 (OMIM 300067), and X-linked lissencephaly 2 (OMIM300215).

### 115.3.2 Isolated Lissencephaly Sequence and the Miller-Dieker Syndrome

The most common cause of classical lissencephaly is a mutation of an autosomal gene on chromosome 17p13

known as *LIS1*. Deletion or mutation in the *LIS1* gene is the cause of lissencephaly both in MDS and in ILS (139). Additional clinical findings in MDS include an abnormal facies with microcephaly, bitemporal hollowing with narrowing at the temples, tall and prominent forehead with vertical furrowing, hypertelorism with upward slanting palpebral fissures and ptosis, short nose with upturned nares, low-set ears with minor flattening of the helices, prominent philtrum with thin vermilion border of the upper lip, and small mandible (140–142). Digital abnormalities, such as syndactyly, congenital heart disease, and other visceral abnormalities may be seen in patients with MDS (142–144). Almost all children with classical lissencephaly have profound developmental delay and intellectual disability; many of them die during infancy or childhood. The majority of the patients have seizures, typically starting during the first 6 months of life (143,145).

On imaging studies, the cerebral hemispheres show agyria (lack of gyri) or pachygyria (broadening of gyri), and often these two features coexist. The frontal and temporal opercula (the parts of the brain that cover insular cortices) are not developed, leading to a characteristic “figure-eight” shape appearance of the brain on axial images and bitemporal hollowing. Agenesis or hypogenesis of the corpus callosum may be seen, and small midline calcifications in the region of the septum pellucidum may be observed in patients with MDS (140). The cerebellum is notably normal in MDS (146).

**115.3.2.1 Genetics and Biology.** Identification of patients with MDS and monosomy 17p led to a suggestion that this locus may harbor the causative gene (141). This eventually led to the identification of *LIS1*, a gene that is deleted in MDS and deleted or mutated in ILS (139). Subsequent studies showed visible cytogenetic or submicroscopic deletions of 17p13.3 in more than 90% of MDS patients and in approximately 40% of patients with ILS (140). Point mutations as well as intragenic deletions and duplications of *LIS1* have also been identified in patients with ILS (147–150). What distinguishes the group of patients with *LIS1*-associated lissencephaly is a posterior predominance of the gyral abnormality, such that the posterior cortex is essentially agyric while there is typically a pachygyria pattern anteriorly. In ILS, the submicroscopic deletion is smaller than its counterpart in MDS (151,152), and so it has been suggested that MDS may represent a contiguous gene syndrome, with deletion of additional gene(s) being responsible for the dysmorphic features of MDS (140). There are eight genes that are consistently deleted in patients with MDS; deletion of the genes *CRK* and *YWHAE* appears to be associated with more severe lissencephaly (153). Animal studies have also shown that the 14-3-3 epsilon protein encoded by *YWHAE* is important for neuronal migration (154).

Virtually all known *LIS1* mutations are de novo; thus if a deletion or a mutation of the *LIS1* gene is identified

in a patient, the recurrence risk is very low (155). There are rare cases in which one of the parents harbors a balanced translocation in the area involving the *LIS1* gene. In such cases, the risk is significantly higher, and up to 33% of the offspring having an abnormal genotype (i.e. deletion or duplication of 17p) and/or phenotype (156). Originally both Miller (157) and Dieker (158) reported familial cases of MDS, and later studies revealed translocations in both the families they described (159).

The normal cellular function of the *LIS1* protein is thought to be related to regulation of microtubules. Microtubules, which are major components of the cytoskeleton, play a critical role in essential cellular processes, such as cell division and migration. *LIS1* has been known to interact directly with microtubules and stabilize them. *LIS1* also interacts with motor protein dynein (160) and regulates the microtubule-based molecular motor (161–163).

### 115.3.3 X-Linked Lissencephaly 1/ Subcortical Band Heterotopia

A familial, X-linked form of lissencephaly (*LISX1*; OMIM 300067) has also been identified and is associated with a higher recurrence risk than lissencephaly due to *LIS1* mutations. *LISX1* manifests in affected hemizygous males as a disorder quite similar to MDS/ILS, with severe intellectual disability, intractable seizures, classical lissencephaly with pachygyria/agyria, agenesis of corpus callosum, and death during infancy (Figure 115-2) (164). This disorder manifests as a much milder phenotype in heterozygous females, who present with subcortical band heterotopia (SBH; also known as “double cortex” syndrome). SBH is characterized by symmetric stretches of gray matter found in the central white matter between the cortex and the ventricular surface, associated with intellectual disability and epilepsy. There is a wide range of phenotypic severity—both in terms of cognitive outcome and epilepsy—associated with SBH (165).

Although the MRI findings of the brain of *LISX1* patients are generally quite similar to that of MDS/ILS, there is a notable difference in the pattern of malformation. The malformation is more severe posteriorly in patients with *LIS1* mutations and more severe anteriorly in patients with *LISX1* (Figure 115-2) (148,166). In addition, a neuropathological study of two fetuses, one with a *LIS1* mutation and the other with a *DCX* mutation, showed different patterns of cortical lamination in these two conditions, suggesting possibly dissimilar pathogenetic mechanisms in MDS/ILS and *LISX1* (167). Unlike MDS, there is no outward syndromic manifestation of *LISX1* or SBH.

**115.3.3.1 Genetics and Biology.** Linkage analysis of pedigrees with *LISX1*/SBH localized the gene to Xq22 (168,169). The gene responsible for *LISX1*/SBH was identified and named *doublecortin* (*DCX*, OMIM 300121) (170,171). In one study, mutations of

**FIGURE 115-2** T1-weighted sagittal MRI image of a patient with X-linked lissencephaly 1 (*LIS1*) is shown. The anterior cortex almost completely lacks gyri (arrows), but the gyral pattern of the posterior cortex is relatively intact (arrowheads). This is typical of lissencephaly due to *DCX* mutations. In lissencephaly due to *LIS1* mutations, this anterior–posterior gradient is reversed (see text).

*DCX* were identified in all eight familial cases and in 18 of 47 (38%) sporadic cases of SBH (172). Another study found mutations of *DCX* in all 11 familial cases of SBH, and in 22 of 26 (85%) sporadic SBH cases (173). Although most of the reported *DCX* mutations are point mutations, intragenic deletions have been reported (149). Unlike *LIS1* mutations, in which the risk of a second affected child is low, recurrence of either *LIS1* or SBH will be 50% if the mother is affected with SBH due to a *DCX* mutation. Therefore, in males with lissencephaly who do not show deletion or mutation of *LIS1*, mutation analysis of *DCX* should be considered. MRI examination of the mother may reveal SBH, particularly if the mother has epilepsy or cognitive difficulties. Maternal germline mosaic mutations in *DCX* have also been reported (173,174). Together, *LIS1* and *DCX* mutations have been estimated to cause the most cases (approximately 76%) of classical lissencephaly in the United States (148). There are likely to be other lissencephaly loci responsible in the rest of the patients. The presence of an autosomal recessive locus for lissencephaly has been suggested (i.e. Norman-Roberts syndrome; OMIM 257320) (175). It should also be noted that both male and female patients with SBH and somatic mosaic *DCX* mutations have been reported (165,174,176,177). Rare patients with mosaic mutations of *LIS1* presenting with SBH have also been reported (178). In more recent years, mutations in *DCX* have also been associated with a milder range of phenotypes, including nonsyndromic intellectual disability with normal MRI in females (179) and anterior-predominant pachygyria in males (180).

When compared to cases with *LIS1* mutations, cases with *DCX* mutations display variable

neuropathological patterns, some with a six-layer cortex and others with an ill-defined four-layer cortex. In individuals with mutations in *LIS1*, linear disruptions of the gray–white matter junction have been observed; in contrast, individuals with mutations in *DCX* displayed more irregular disruptions of the gray matter–white matter junction as well as nodular heterotopias (181).

*DCX* is expressed in postmitotic neurons throughout the developing nervous system. The *DCX* protein has been shown to interact with and stabilize microtubules (182–184). Note that *LIS1* and *DCX*, two genes that lead to the phenotype of classical lissencephaly, are both involved in the regulation of microtubules. The structure of *DCX* includes two microtubule binding domains in the protein (185). Thus, regulation of microtubules appears to be essential for migration of cortical neurons.

### 115.3.4 Lissencephaly Associated with *TUBA1A* Mutations

Mutations in *TUBA1A*, which encodes the microtubule-related protein  $\alpha$ -tubulin, have been associated with a wide range of cerebral malformations including lissencephaly (OMIM 611603) (186,187,337). The prototype of *TUBA1A*-associated lissencephaly includes additional abnormalities of the hippocampi, corpus callosum, brainstem, and cerebellum (187). Abnormalities in the basal ganglia have been seen as well in some cases (188). Histological findings in severe cases with mutations in *TUBA1A* include abnormal lamination of the cerebral cortex and hippocampi as well as heterotopic and misoriented neurons in the cortex (188). After several cases with varying degrees and patterns of lissencephaly were screened for mutations in *TUBA1A*, the spectrum of *TUBA1A*-associated lissencephaly has come to include a mild form with perisylvian pachygyria as well as a more severe form consisting of posteriorly predominant pachygyria (with a gradient similar to that seen in association with *LIS1* and *ARX*), microcephaly, cerebellar hypoplasia, and abnormalities of the anterior limb of the internal capsule (186,189). The associated phenotype is reported to include intellectual disability; the proportion of patients with mutations in *TUBA1A* with epilepsy is not yet reported but is expected to be very high.

While *TUBA1A* is relatively new to the lissencephaly genetic landscape, it is really not surprising, given the microtubule-associated roles of *LIS1* and *DCX*, that a gene encoding  $\alpha$ -tubulin would be associated with a defect in migration resulting in lissencephaly. Interestingly, similar to what has been observed for *ARX*, there have been abnormalities in interneuron migration suggested by the observation of decreased numbers of interneurons in a fetus with a known mutation in *TUBA1A* (188).

### 115.3.5 X-Linked Lissencephaly 2 (X-Linked Lissencephaly with Abnormal Genitalia)

There is another form of X-linked lissencephaly (X-linked lissencephaly 2, also known as X-linked lissencephaly with abnormal genitalia; LISX2; OMIM 300215). In a typical patient with LISX2, lissencephaly is associated with agenesis of the corpus callosum and ambiguous or underdeveloped genitalia (190–192). The causative gene for this syndrome was identified as the Aristaless-related homeobox transcription factor gene, *ARX* (193). *ARX* has been shown to regulate tangential migration of interneurons (193–196). It is also implicated in regulation of neuronal proliferation (193,195). In addition to LISX2, mutations in the *ARX* gene can cause a wide variety of syndromes, ranging from severe brain malformations, such as hydranencephaly, to neurological disorders with apparently normal brain structure, such as West syndrome, nonsyndromic intellectual disability or autism (197–199). There seems to be some degree of genotype–phenotype correlation in that mutations that cause premature termination are more likely to be seen in patients with overt malformations and mutations that cause polyalanine expansion are commonly seen in patients without malformations (197).

While the pattern of lissencephaly associated with *ARX* mutations is a posterior-predominant agyria, with a gradient similar to what is seen in the setting of *LIS1* mutations, there are several features that may distinguish the two: (1) a cell-sparse layer is observed with *LIS1*, but brains from patients with mutations in *ARX* have only three cortical layers and lack a cell-sparse zone (181); (2) agenesis of corpus callosum is commonly seen with *ARX* mutations (197); and (3) the basal ganglia are noted to be small in patients with lissencephaly due to *ARX* mutations (198).

### 115.3.6 Lissencephaly with Cerebellar Hypoplasia

A variety of types of lissencephaly with cerebellar hypoplasia have been defined (200), and one of them, an autosomal recessive form of lissencephaly with severe hypoplasia of the cerebellum, has been characterized genetically (201–203). Since no postmortem studies on this condition have been published, it is unknown whether it resembles type I lissencephaly microscopically or whether it shows a unique histological pattern. Mutations in a gene called *reelin* (*RELN*) have been identified in two families with this condition (204). The *RELN* gene had previously been identified in mouse as causing the *reeler* mutation, which is characterized by disorganized cortical lamination and severe hypoplasia of the cerebellum (205). Therefore, it is likely that the histological pattern in humans reflect similar defects. Reelin is a protein secreted by Cajal-Retzius cells, which are the specialized neurons that reside in the uppermost

layer of the cerebral cortex. Although there is evidence that Reelin acts as a “stop” signal for migrating neurons, the precise mechanism through which Reelin regulates neuronal migration is yet to be understood (206). Very-low-density lipoprotein receptor (VLDLR) and low-density lipoprotein receptor-related protein 8 (LRP8; also known as apolipoprotein E receptor -2) have been shown to act as receptors for Reelin (207), and mutations in the *VLDLR* gene have been associated with cerebellar hypoplasia similar to that seen with *RELN* mutations (208,209). Simplification of gyral pattern appears less severe in patients with *VLDLR* mutations.

### 115.3.7 Cobblestone Dysplasia

Cobblestone dysplasia is characterized by disorganized cortical layers, overmigration of neurons onto the outside of the brain through breaches in the pial surface, and gliovascular proliferation (210,211). The term “cobblestone” is applied because the ectopic neurons with gliovascular proliferation near the surface of the cortex give a bumpy cobblestone-like appearance. It has previously been called “type II lissencephaly” or “cobblestone lissencephaly.” The gyral pattern seen on imaging studies varies widely, including polymicrogyria, pachygyria, and agyria, therefore, the term “cobblestone dysplasia” appears to be more appropriate.

Cobblestone dysplasia is the characteristic brain malformation observed in a group of disorders, sometimes referred to as “dystroglycanopathies,” which includes three prototypic autosomal recessive disorders: Fukuyama congenital muscular dystrophy (FCMD), Walker-Warburg syndrome (WWS), and muscle-eye-brain disease (MEB). All three syndromes associated with cobblestone dysplasia affect the brain, muscle, and eye. As the genetic studies of these disorders progressed, it became clear that there was significant clinical and genetic overlap among these conditions. Since the fundamental biological defects in these disorders appear to be defects in glycosylation of  $\alpha$ -dystroglycan, the term dystroglycanopathy has been coined.

FCMD is most prevalent in Japan, although rare cases have been reported from other countries (212–214). It presents with hypotonia during infancy, generalized weakness, intellectual disability, and occasionally seizures (215). WWS has been reported worldwide and has generally a much more severe phenotype. Patients with WWS often present with severe hypotonia and lethargy during the neonatal period. Median survival in one study was 9 months (216). Various forms of eye abnormalities are seen, including retinal nonattachment/detachment, retinal dysplasia, cataract, persistent hyperplastic primary vitreous, microphthalmia, and coloboma (216–218). MEB is prevalent in Finland, although it has been reported in many countries. Patients with MEB often present with neonatal hypotonia and weakness, which develops into spasticity and contractures (219). Severe intellectual disability is the

rule, and eye abnormalities include severe visual failure and myopia (219).

On imaging studies, regions of cobblestone dysplasia usually appear as agyric or pachygyric areas. In typical FCMD, the frontal lobes show polymicrogyria, and cobblestone dysplasia is limited to the temporo-occipital area (220,221). WWS presents more dramatically, with diffuse agyric or pachygyric areas (representing cobblestone dysplasia), enlarged ventricles, hypoplasia of the pons and cerebellar vermis, fusion of the superior and inferior colliculi, and a diffuse abnormality of the cerebral white matter (Figure 115-3) (221,222). Imaging findings of MEB are similar to that of WWS, but abnormalities are usually less extensive (221–224). Cerebellar polymicrogyria with or without small cysts can be seen in any of these disorders.

**115.3.7.1 Genetics and Biology.** Linkage mapping assigned the FCMD gene to 9q31 (225,226); subsequently the causative gene termed *FKTN* (*fukutin*) was cloned (227) and appears to encode a glycosyltransferase. Most (87%) FCMD-bearing chromosomes have been derived from a single mutation consisting of a retrotransposon insertion in the 3' untranslated region, suggesting an ancestral founder mutation in the Japanese population (227). Patients who are compound heterozygotes, carrying this founder mutation and a point mutation, have been found to be more likely to have severe phenotypes, including a WWS-like phenotype (228). Patients who are homozygous for nonfounder mutation have been reported, and the phenotype resembles WWS (229–231). These data suggest that the Japanese founder mutation may represent a partial loss-of-function allele. Subsequently, mutations in a gene with sequence similarity to *FKTN*, *FKRP*

(fukutin-related protein), have been identified in patients with WWS- and MEB-like phenotypes (232).

The first reported gene for the MEB phenotype was linked to 1p34-p32 (233). Subsequently, the responsible gene in this locus was identified as *POMGNT1* (protein O-mannose beta-1, 2-N-acetylglucosaminyltransferase) (234). The identification of an MEB gene as a glycosyltransferase made other glycosyltransferases potential candidate genes for this group of disorders. Indeed, another glycosyltransferase, *POMT1* (protein O-mannosyltransferase), was found to be mutated in some patients with WWS (235). However, *POMT1* mutations seem to account for only a minority of cases of WWS, possibly as low as 7% (231,236). Subsequently, mutations in several other genes have been associated with WWS and MEB-like phenotypes. These include *FKRP* (fukutin-related protein) (232,237), *POMT2* (238–240) and *LARGE* (241–243). In one series, nine of 27 European and American patients with WWS were accounted for by mutations in *POMT1*, *POMT2*, *FKTN* and *FKRP*, and five of those cases were due to *FKTN* mutations (231).

*POMT1*, *POMT2* and *POMGNT1* are glycosyltransferases, and although the biochemical functions of *FKTN*, *FKRP* and *LARGE* are not completely elucidated, they appear to play essential roles in  $\alpha$ -dystroglycan glycosylation. Animal studies have suggested that functional disruption of dystroglycan may be central to the CNS pathogenesis of these disorders (244). Hypoglycosylation of  $\alpha$ -dystroglycan has been shown in patients with FCMD and MEB, and this abolishes binding activity of dystroglycan for ligands such as laminin, neurexin, and agrin (245). Thus, it may be speculated that this defect in binding leads to loss of integrity of the pial surface and that subsequent overmigration of neurons through these breaches leads to the development of cobblestone dysplasia.

**FIGURE 115-3** T2-weighted axial image of a patient with Walker-Warburg syndrome is shown. Enlarged lateral ventricles are evident. The gyral pattern seen here is mostly agyria (absence of gyri), but some areas show pachygyria (broadened gyri; arrows).

### 115.3.8 X-Linked Periventricular Heterotopia

Gray matter heterotopias are masses of well-differentiated neurons in abnormal locations, reflecting arrested radial neuronal migration. Periventricular heterotopia (PH) can be encountered as a sporadic condition, but there are several genetic syndromes in which heterotopias are a cardinal feature. One such syndrome is X-linked PH (OMIM 300049), for which many familial cases are known (246–249). In these pedigrees, typically only females were affected and there was a high rate of miscarriages among the affected females. These observations led to the suggestion that the condition was an X-linked disorder with prenatal lethality in males (247).

Females affected with X-linked PH typically present with epilepsy, commonly generalized tonic-clonic or complex partial seizures. Typical age of onset is before the mid-twenties, and the average age is around 15 years.

Intelligence is usually normal, although some patients have borderline intellectual disability, and dyslexia is remarkably common (250,251). An increased incidence of patent ductus arteriosus and stroke at young ages has been noted (252). Abnormalities in cardiac valve development have also been reported in some cases (252,253), and an increasing number of affected patients have vascular manifestations of Ehlers-Danlos syndrome (254).

Brain MRI of affected females typically shows bilateral PH nodules, which show the typical signal characteristics of normal gray matter. Pathologically, brains of females with X-linked PH show continuous bands or discontinuous nodules of gray matter along the periventricular region, consisting of well-differentiated cortical neurons (255). The heterotopic subependymal nodules of X-linked PH may initially be misdiagnosed as TSC nodules (256), but classical lesions of X-linked PH appear as roughly symmetric nodules as opposed to the less-confluent and not necessarily symmetric nodules of TSC.

**115.3.8.1 Genetics and Biology.** X-linked PH was mapped to distal Xq28 (255), and subsequently mutations in the *FLNA* (*filamin A*) gene were identified to be the cause (252). Mutations in *FLNA* have been identified in almost 100% of familial cases of X-linked PH (257,258) and 26% of sporadic patients with classical bilateral nodular PH (257). In rare instances, male patients with PH have *FLNA* mutations, but the majority of male patients are negative for *FLNA* mutations (257,258). *FLNA* mutations have also been identified in patients with PH and coexisting Ehlers-Danlos syndrome (OMIM300537) (254) and X-linked chronic idiopathic intestinal pseudo-obstruction with CNS involvement (OMIM300048) (259). In recent years, the clinical spectrum of *FLNA* mutations has expanded to include conditions in which non-CNS involvement predominates or in which no CNS involvement is noted. For example, *FLNA* mutations that preserve the reading frame have been shown to be associated with otopalatodigital syndrome types 1 (OMIM311300) (260) and 2 (OMIM304120) (260), frontometaphysial dysplasia (OMIM305620) (260), Melnick-Needles syndrome (OMIM309350) (260), FG syndrome-2 (OMIM300321) (261), terminal osseous dysplasia (OMIM300244) (262), and cardiac valvular dysplasia (OMIM314400) (263). This suggests that *FLNA* is involved in a broad range of organogenesis involving the nervous, skeletal, and cardiovascular systems. It has been speculated that the mutations associated with some of these syndrome may be gain-of-function mutations affecting specific protein interactions (260,264), unlike mutations associated with PH, which are probably loss-of-function mutations.

*FLNA* encodes a large cytoplasmic actin-binding protein that was originally identified in macrophages as a protein that precipitated actin (265). It had been shown to be essential for migration in non-neuronal cell types (266,267), but its role in neuronal migration had

not been known prior to identification of mutation in patients with X-linked PH. *FLNA* is expressed by the cortical neurons during migration (252,268) and possibly regulates the actin cytoskeleton in response to the extracellular signals during neuronal migration (269).

### 115.3.9 Other Genetic Heterotopia Syndromes

An autosomal recessive syndrome with heterotopia associated with microcephaly (OMIM 608097) was found to be caused by mutation in the ADP-ribosylation factor guanine nucleotide-exchange factor-2 gene (*ARFGEF2*) (270). This gene functions in vesicle and membrane trafficking from the trans-Golgi network (TGN) and appears to be essential for proliferation of neuroblasts and migration of postmitotic neurons (270). PHs have been seen in association with various chromosomal anomalies. These include chromosome 5p anomalies (271), 5q deletion (272), 7q11.23 deletion (273), and 1p36 deletion (273,274).

## 115.4 MALFORMATIONS DUE TO ABNORMAL CORTICAL ORGANIZATION

### 115.4.1 Polymicrogyria

Polymicrogyria refers to a cortical malformation characterized by numerous small gyri. Clinical presentations of polymicrogyria depend on the extent and location of the abnormal cortex. When the abnormality is diffuse, severe developmental delay is the rule, but when it is focal, developmental delay is less severe (104). Some individuals with small regions of focal polymicrogyria have normal intelligence. Seizures are common in both groups. On MRI, small meandering gyri of polymicrogyric cortex may appear as thickened cortex, and it may be difficult to distinguish from “pachygyria” (thickened cortex). Irregularity of the junction between the cortex and white matter is usually evident with high-resolution imaging (275,276).

In recent years, several distinctive syndromes of polymicrogyria have emerged (277). These syndromes, which are mainly distinguished by characteristic distributions of polymicrogyric cortex, include bilateral frontoparietal polymicrogyria (BFPP; OMIM 606854) (278), congenital bilateral perisylvian syndrome (CBPS; OMIM 300388; also known as bilateral perisylvian polymicrogyria (BPP)) (279), bilateral generalized polymicrogyria (BGP) (280), and bilateral occipital polymicrogyria (OMIM 612691) (281).

BFPP is associated with symmetrical distribution of polymicrogyria in the frontal and parietal cortex (Figure 115-4). The clinical presentation includes moderate to severe developmental delay, seizures (usual onset after 4–5 years), bilateral pyramidal and cerebellar signs, and dysconjugate gaze (278). CBPS is characterized by

**FIGURE 115-4** T1-weighted axial MRI image of a patient with bilateral frontoparietal polymicrogyria is shown. The frontoparietal cortex shows an abnormal gyral pattern (arrowheads), which represents clusters of abnormal small gyri. The occipital cortex appears typically spared in this condition, and appears relatively normal in this image. Mutations in *GPR56* are responsible for the condition.

diplegia of the facial, pharyngeal, and masticatory muscles, which can be explained by the location of abnormal cortex (282). Intellectual disability is common, but the severity ranges from mild to severe. Epilepsy is also common, and typically has its onset between 4 and 12 years of age (283). BGP is characterized by motor and cognitive delay, and seizures are frequent. Dysconjugate gaze, which is commonly seen in BFPP, or pseudobulbar palsy, which is a hallmark of CBPS, is not typically seen in BGP (280). A comprehensive review of the clinical features of 328 cases of polymicrogyria revealed that seizures occurred in 78%, global developmental delay in 70% and microcephaly in 50%; generally, the more severely affected children had more widespread polymicrogyria and earlier age at presentation with epilepsy or other neurological symptoms (277).

**115.4.1.1 Genetics and Biology.** Polymicrogyria is usually encountered as a sporadic condition; however, it has become evident that there are distinct genetic syndromes with polymicrogyria. Polymicrogyria in association with chromosome 22q11 deletions have been well documented (284,285,338), although only a minority of the patients with 22q11 deletion have polymicrogyria. Furthermore, recurrent copy number variations at 1p36.3, 2p16.1-p23.1, 4q21.21-q22.1, 6q26-q27, and 21q2 have been reported in patients with polymicrogyria (286), suggesting that genes in these regions may be involved in brain development, particularly proper cortical organization. It is important to note that the majority of individuals with polymicrogyria associated with these copy number variants displayed dysmorphic features that today would prompt evaluation with a chromosomal microarray to assess for deletions or duplications.

BFPP, originally described under several different monikers, is often seen in consanguineous pedigrees, suggesting

autosomal recessive inheritance (202,287–291). BFPP was mapped to 16q12.2-21 (292), and subsequently the causative gene was identified (293). The gene mutated in BFPP, *GPR56*, encodes a G-protein coupled receptor, whose ligand is not identified yet. *GPR56* appears to be essential for maintaining the integrity of pial basement membrane (294), and therefore the pathogenesis of BFPP appears to overlap with that of cobblestone dysplasia (see Section 115.3.7). BFPP is increasingly recognized as sharing radiographic and pathologic features with cobblestone dysplasia (295).

Recently, mutations in *LAMC3*, encoding a laminin protein that is characteristic of the pial basement membrane, has also been discovered in association with polymicrogyria in the occipital region (296). This adds to the evidence suggesting that disruption of the pial basement membrane is a common cause of polymicrogyria.

There have been many reports of familial cases of CBPS (279). Many pedigrees were found to be consistent with an X-linked mode of inheritance or autosomal dominant inheritance with incomplete penetrance, and genetic loci for CBPS have been identified at Xq28 (297) and Xq27 (298); however, other genetic loci may exist for this syndrome. Some patients with BGP are siblings and/or born to consanguineous parents, suggestive of autosomal recessive inheritance (280). In familial BGP cases, linkage to the BFPP locus on 16q has been ruled out, but the locus for BGP has not been identified (280).

There is also evidence that prenatal insults, such as hypoxic-ischemic injury, can lead to polymicrogyria. Polymicrogyria in some of these cases has been suggested to result from postmitotic encephaloclastic lesion (299,300), but animal studies have indicated that cortical injuries resulted in polymicrogyria only when they occurred during the course of migration (301–303). Other types of intrauterine insults (e.g. cytomegalovirus infection) and metabolic disorders (see below) have been associated with polymicrogyria as well, but genetic forms of polymicrogyria always need to be considered. For example, bandlike calcification of the brain with simplified gyral pattern and polymicrogyria (OMIM 251290), which resembles TORCH (Toxoplasmosis, Other, Rubella, Cytomegalovirus, Herpes simplex virus) infection and sometimes referred to as pseudo-TORCH syndrome, is associated with mutations in a tight-junction protein gene, *OCN* (304). Interestingly, a mutation in another tight-junction protein gene *JAM3* has been reported to cause calcification of the brain (OMIM 613730) (305). Patients with a mutation in *JAM3* often had severe perinatal intracranial hemorrhage, but no obvious polymicrogyria was noted.

Two families have been reported with perisylvian polymicrogyria and mutations in the sushi-repeat-containing gene *SRPX2*, located at Xq22; one mutation (N327S) was found in a French family presenting with rolandic seizures, oral and speech dyspraxia, and variable degrees of intellectual disability, and a second mutation (Y72S)

was reported in a male patient with seizures of the rolandic area and BPP whose female relatives with the same mutation had only mild intellectual disability without polymicrogyria (306).

### 115.4.2 “Tubulinopathies” and Polymicrogyria

As mentioned above, *TUBA1A* is a gene encoding a microtubule-related protein that is associated with brain malformations, typically lissencephaly with other features. Recent work suggests that mutations in *TUBA1A* are also responsible for some cases of BPP (187,189). Although it is not a common cause of BPP, the association between this gene—known to be involved in cortical migration—and a defect such as polymicrogyria that is thought to reflect a disorder of later cortical organization speaks to the idea that many of the genes in brain development are important through multiple stages of brain development. Along the same lines, mutations in the gene encoding  $\beta$ -tubulin, *TUBB2B*, have been reported in five cases of asymmetrical polymicrogyria (OMIM 610031) (307). Mutations in *TUBA8* have been implicated in a form of polymicrogyria associated with optic nerve hypoplasia (OMIM 613180) (308). Additionally, mutations in the gene *TUBB3* have been seen in cases of frontally predominant polymicrogyria associated with basal ganglia dysmorphism, corpus callosum abnormalities, and mild brainstem hypoplasia (309) without the feature of congenital fibrosis of the extraocular muscles reported in the original description of *TUBB3* mutations (310).

### 115.4.3 Schizencephaly

The term “schizencephaly” (OMIM 269160) was coined by Yakovlev and Wadsworth in 1946 and refers to a brain malformation characterized by full-thickness cleft of the cerebral mantle (311,312). The walls of the clefts are usually lined by polymicrogyric cortex. As Yakovlev and Wadsworth proposed, schizencephaly can be divided into two subtypes, namely closed-lip schizencephaly and open-lip schizencephaly. In closed-lip schizencephaly, two walls are in apposition and form a so-called “pial-ependymal seam.” On the other hand, in open-lip schizencephaly the two walls are apart and the space between the two walls is filled with cerebrospinal fluid (CSF) (Figure 115-5). The clinical presentation varies depending on the extent and location of anatomical abnormalities. Closed-lip schizencephaly often presents with hemiparesis or motor delay, and open-lip schizencephaly may present with the same features as well as seizures (313). Generally, the severity of motor and/or cognitive impairment is related to the extent of anatomic malformation; however, the presence or severity of epilepsy may not be predicted from the extent of the anatomical abnormality. Although schizencephaly is usually seen as sporadic cases, rare familial cases have been reported (314–318).

**FIGURE 115-5** T2-weighted axial MRI image of a patient with bilateral open-lip schizencephaly is shown. The walls of the full-thickness clefts are lined by abnormal cortices (arrows), which often prove to be polymicrogyria histologically.

The presence of *de novo* heterozygous mutations in the *EMX2* gene has been reported in sporadic and familial cases of schizencephaly (319–321); however, subsequent sequencing effort failed to identify any pathogenic *EMX2* mutation in a total of more than 100 patients with schizencephaly (322,323). Thus the role that *EMX2* plays in pathogenesis of schizencephaly is not entirely clear. Recently, a few patients with *WDR62* mutations were found to have schizencephaly as well as microcephaly (32,34), but the proportion of cases of schizencephaly caused by *WDR62* mutation is not known. Schizencephaly can also definitely be caused by nongenetic etiology, such as the death of monozygotic cotwin (324), and is associated with environmental risk factors, such as in utero exposure to warfarin, alcohol and cocaine and young maternal age (324), to a much greater extent than any other cortical malformation, suggesting a substantial role for nongenetic factors as well.

## 115.5 MALFORMATIONS OF CORTICAL DEVELOPMENT, NOT OTHERWISE CLASSIFIED

### 115.5.1 Malformations Secondary to Inborn Errors of Metabolism

Typically, inborn errors of metabolism cause degenerative cerebral lesions; however, several metabolic disorders are associated with developmental malformations of the cerebral cortex. For example, neuronal migration abnormalities, particularly perisylvian pachygyria-polymicrogyria, are a prominent feature of Zellweger syndrome (325–328). Pathological studies have shown abnormal pleomorphic cytosomes, presumably the results of excessive very-long-chain fatty acids, in astrocytes, neuroblasts, immature neurons and radial glia,

suggesting linkage between the underlying biochemical abnormality and migrational disturbances (326). Studies of an animal model of Zellweger syndrome have suggested that peroxisomal function in both brain and extraneuronal tissues is important to the normal neuronal migration (329).

Other inborn errors of metabolism associated with developmental disorders of the cerebral cortex include multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type II; OMIM 231680) (330) as well as mitochondrial disorders and disorders of pyruvate metabolism (331–334). The pathogenesis of cortical dysgenesis in these disorders is not well understood. Amish lethal microcephaly (OMIM 607196) is a metabolic disorder reported among the Old Order Amish of Lancaster County, Pennsylvania. The patients have severe congenital microcephaly and 2-ketoglutaric aciduria; they typically die within the first year of life. This is one of the few known metabolic disorders that are associated with congenital, rather than postnatal, microcephaly. The causative gene is *SLC25A19* (335), which may be involved in mitochondrial thiamine pyrophosphate transport and affects the function of the  $\alpha$ -ketoglutarate complex (336). Other metabolic causes of congenital microcephaly include maternal phenylketonuria and phosphoglycerate dehydrogenase deficiency (24).

## 115.6 CONCLUSIONS

Recent years have seen dramatic progress in the area of genetic malformations of the cerebral cortex. As more and more genes for brain malformations are identified, clinical syndromes are being redefined based on their underlying genetic basis. Although some of the disorders presented here are rare, they collectively account for a large number of patients with neurological disabilities. Identification of the causative genes has already led us toward the development of genetic testing and better genetic counseling for the patients and their families. In addition, studying the functions of these genes continues to lead to a better understanding of biological mechanisms of the human brain development. There still remains a stunning diversity of genetic disorders of cortical development that are yet to be characterized and studied, and each year brings further progress in understanding the genetic basis of many of those disorders. With the advent of next-generation sequencing, we expect to see an ever-increasing number of genes involved in brain development identified and characterized through the study of human cerebral malformation syndromes.

## ACKNOWLEDGMENTS

GHM and CAW are supported by a Collaborative Research Grant from the Dubai Harvard Foundation for Medical Research. AP is supported by the NINDS (K23NS069784). CAW is supported by grants from the

NINDS (R01NS35129 and R01NS032457), the NIMH (R01MH083565 and RC2MH089552), the Fogarty International Center (R21TW008223), the Manton Center for Orphan Disease Research, the Nancy Lurie Marks Family Foundation and the Simons Foundation. CAW is an investigator of the Howard Hughes Medical Institute. The authors thank Dr. Mohamed A. Sabry for his contribution to this chapter in the previous editions.

### Biographies

**Dr Ganeshwaran H Mochida, MD, MMSc** is a Staff Scientist in the Division of Genetics at Boston Children's Hospital, Assistant in Neurology at Massachusetts General Hospital, and Assistant Professor of Pediatrics at Harvard Medical School. He is a native of Tokyo and graduated from Keio University School of Medicine. After his pediatric internship at Keio University Hospital, Dr Mochida moved to Boston and completed residency training in pediatric neurology at Massachusetts General Hospital. Subsequently, his postdoctoral research training was in the laboratory of Professor Christopher A Walsh at Harvard Medical School and its affiliated hospitals. His research interests include genetic mechanisms of human microcephaly and intellectual disability syndromes, with an emphasis on bridging the gap between the knowledge of molecular mechanisms of brain development and the management of human neurological disorders.

**Dr Annapurna Poduri, MD, MPH** is an Instructor in Neurology at Harvard Medical School and Assistant in Neurology at Boston Children's Hospital in the Division of Epilepsy and Clinical Neurophysiology. She received her BA in Biology from Harvard and MD from the University of Pennsylvania School of Medicine. She received her residency training in pediatrics at Boston Children's Hospital and child neurology at the Children's Hospital of Philadelphia. She completed her fellowship in clinical neurophysiology at Children's Hospital Boston and then pursued postdoctoral training in the genetics of brain malformations in the laboratory of Professor Christopher A Walsh. Her primary research interest is the genetics of inherited epilepsies.

**Dr Christopher A Walsh, MD, PhD** is Bullard Professor of Pediatrics and Neurology at Harvard Medical School, Chief of the Division of Genetics at Boston Children's Hospital, and an Investigator of the Howard Hughes Medical Institute. He completed his MD and PhD degrees at the University of Chicago. After a neurology residency and chief residency at Massachusetts General Hospital, he completed a fellowship in genetics at Harvard Medical School. He joined the faculty at Harvard Medical School in 1993 and has held the Bullard Professorship since 1999. Dr Walsh's research has focused on the development, evolution, and function of the cerebral cortex. He has pioneered the analysis of human genetic diseases that disrupt the cerebral cortex, including autism, intellectual disability, seizures, and cerebral palsy, identifying genetic causes for more than a dozen brain diseases of children. Among his awards are a Jacob Javits Neuroscience Investigator Award (National Institute of Neurological Disorders and Stroke), the Dreifuss-Penry Award Epilepsy Research Award (American Academy of Neurology), the Derek Denny-Brown Award and the Jacoby Award (American Neurological Association), the Research Award (American Epilepsy Society), and the Wilder Penfield Award (Middle Eastern Medical Assembly). He is an elected member of the American Neurological Association, the American Association of Physicians, and an elected fellow of the American Association for the Advancement of Sciences.

### ABBREVIATIONS

ACH – acetylcholine  
 AD – autosomal dominant  
 ADNFLE – autosomal dominant nocturnal frontal lobe epilepsy  
 ADPEAF – autosomal dominant partial epilepsy with auditory features  
 AED – antiepileptic drug  
 AGAT – arginine glycine amidino transferase  
 ANT1 – adenine nucleotide translocator 1  
 AR – autosomal recessive  
 ARFGEF2 – ADP-ribosylation factor guanine nucleotide-exchange factor-2  
 ARX – aristaless-related homeobox  
 AS – angelman syndrome  
 BECTS – benign epilepsy with central temporal spikes  
 BFIC – benign familial infantile convulsions  
 BFNC – benign familial neonatal convulsions  
 BFNIS – benign familial neonatal-infantile seizures  
 BTD – biotinidase  
 CACN1H – calcium channel  
 CAE – childhood absence epilepsy  
 CGH – comparative genomic hybridization  
 CHRNA4 – nicotinic cholinergic receptor alpha 4 subunit  
 CLCN – chloride channel  
 CNS – central nervous system  
 CPS – complex partial seizures  
 CSTB – cystatin B  
 DCX – doublecortin gene  
 DRPLA – dentatorubro-pallidoluysian atrophy  
 DS – Down syndrome  
 DZ – dizygotic twin  
 EEG – electroencephalogram  
 EPM1, EPM2 – epilepsy, progressive myoclonic, type 1/2  
 EPTP – epitempin  
 FEB1-4 – febrile seizure gene loci  
 FLNA – filamin A

FS – febrile seizures  
 GABAA – gamma aminobutyric acid receptor type A  
 GABAB – gamma aminobutyric acid receptor type B  
 GABARA1 – gamma aminobutyric acid receptor alpha 1 subunit  
 GABARG2 – gamma aminobutyric acid receptor gamma 2 subunit  
 GAMT – guanidino acetate methyl transferase  
 GEFSP – generalized epilepsy with febrile seizures plus  
 GLUT1 – glucose transporter 1  
 GTC – generalized tonic clonic seizures  
 hMASS1 – human ortholog, monogenic audiogenic seizure susceptibility gene  
 IGE – idiopathic generalized epilepsy  
 ILAE – International League Against Epilepsy  
 JAE – juvenile absence epilepsy  
 JME – juvenile myoclonic epilepsy  
 KCNQ2 – potassium channel  
 LGI1 – leucine rich glioma inactivated gene 1  
 M CURRENTS – muscarinic currents  
 MECP2 – methyl CPG-binding protein  
 MELAS – mitochondrial encephalopathy, lactic acidosis and stroke  
 MERRF – myoclonic epilepsy with ragged red fibers  
 MIM – Mendelian inheritance in man  
 MLPA – multiplex ligation-dependent probe amplification  
 MTHFR – methylenetetrahydrofolate reductase  
 MZ – monozygotic twin  
 NCL – neuronal ceroid lipofuscinosis  
 NFLE – nocturnal frontal lobe epilepsy  
 NH – nodular heterotopia  
 NHLRC1 – NHL repeat containing gene 1  
 NKH – nonketotic hyperglycinemia  
 PAS – periodic acid-Schiff  
 PH – periventricular heterotopia  
 SBH – subcortical band heterotopia  
 SCN2A – sodium channel  
 SLC2A – solute Carrier Family 2, Member 1

SMEI – severe myoclonic epilepsy of infancy  
 SNPs – single nucleotide polymorphisms  
 SPS – simple partial seizures  
 TNEP1/C21LRP – chromosome 21 leucine rich protein  
 TSC – tuberous sclerosis  
 TWINKLE – novel mitochondrial protein helicase  
 UBE3A – ubiquitin protein ligase E3A  
 VLGR1 – very large G protein-coupled receptor 1  
 VPA – Valproic acid  
 WHS – Wolf–Hirschhorn syndrome  
 XLIS – X linked lissencephaly

## 116.1 INTRODUCTION

Epilepsy is common, and affects 1% of the world population. The term “epilepsy” is drawn from the Greek word “*Epilambanein*”—that means to seize upon. In medical writings as early as 400 B.C., epilepsy was accorded the status of “*a sacred disease*”. The disorder is far reaching in its impact as fear, social stigma, and isolation taint affected individuals and families even today (1).

Human epilepsy is heterogeneous in origin; acquired causes (trauma, tumor, infection, vascular insufficiency, metabolic and drug induced encephalopathies) account for a third of all cases, in the remaining two thirds, a specific etiology is obscure (2). In the Rochester epidemiology project, the cause of epilepsy was presumed to be “idiopathic” in 68% of the incidence cases (1935–1984) signifying that familial/genetic factors were considered as contributory (3). The first human epilepsy gene (mutation involving a nicotinic cholinergic receptor subunit) associated with an idiopathic partial epilepsy syndrome (autosomal dominant nocturnal frontal lobe epilepsy) was identified in 1995 (4). With the convergence of bioinformatics, and high throughput technologies, rapid progress has been made possible in the identification of gene defects for many disorders including epilepsy. The use of microarray technology, next generation rapid sequencing technologies and exome sequencing will further enhance our knowledge about pathogenic gene mutations, and mechanisms underlying gene expression, and regulation of the level and timing of expression (5).

In this chapter, we will highlight the advances in our understanding of the genetic basis of epilepsy, its relevance in the evaluation and management of patients with epilepsy in the clinical setting.

## 116.2 EPILEPSY: DEFINITION

“Epilepsy” is recognized as a disorder in which recurrent seizures occur, accompanied by a variety of clinical phenomena involving motor, sensory, cognitive, psychic and autonomic manifestations, with or without loss of consciousness. The occurrence of at least two unprovoked seizures are necessary to fulfill generally accepted criterion to establish the diagnosis of epilepsy.

## 116.3 EPILEPSY: NEUROPHYSIOLOGICAL BASIS

The central nervous system (CNS) functions as a complex interconnected neuronal network. The clinical manifestations of epilepsy result from hypersynchronous firing of neurons within such cortical networks. Regions of hyperexcitability capable of spontaneous and aberrant behavior can be identified within epileptogenic foci. Intracellular recordings from neurons in such foci demonstrate the occurrence of spontaneous synchronized depolarization of large amplitude (paroxysmal depolarization shift), which is considered the electrophysiological equivalent of the epileptic spike seen on the electroencephalogram (EEG) (6).

Normally, this regional expression of hyperexcitability is limited and constrained by counterbalancing inhibitory processes within the brain. Under pathological conditions, simultaneously occurring increments in excitatory influences accompanied by decrements in inhibitory effects could potentially lead to an unstable electrical state, promoting cortical hyperexcitability and regional spread of excitation. Ultimately, the recruitment of increasing number of neurons and propagation of aberrant excitability through neuronal networks to other regions underlie the diverse seizure semiology encountered in the form of partial and/or complex partial seizures.

The anatomic substrate of a generalized spike wave discharge seen on the EEG in generalized epilepsies involves synchronization between neocortical pyramidal neurons, thalamic relay neurons, and GABAergic neurons of the nucleus reticularis thalami. Current electrophysiological and imaging studies in humans and animal models suggest that the entire brain is not involved homogeneously and the generation of generalized spike wave discharges do not involve a single common pathway or mechanism. Selective thalamocortical network loops are involved in the generation of the typical spike wave discharges in certain forms of generalized epilepsies, while focal or regional aberrations within cortical networks may be sufficient to provoke a transition to generalized spike waves from normal rhythms within thalamocortical networks (7).

Thus, the epileptic seizure represents an endpoint of the interactions between anatomical, biochemical, molecular and electrophysiological changes leading to the generation of cortical hyperexcitability within neuronal networks and spread of excitation along different pathways.

## 116.4 EEG IN EPILEPSY

The EEG records at the scalp surface are the patterns generated by electrical potentials within the brain. These potentials are amplified several thousand times and can be visually analyzed using analog (old, paper

based) and digital instruments (current). The presence of epileptiform patterns on the EEG record, pattern and morphology (sharps, spikes and spike and wave complexes), location/distribution, provide diagnostic clues that help distinguish focal from generalized seizures. We now associate specific epileptiform patterns with certain epilepsy syndromes, given the right clinical context. Some common examples are the finding of a “generalized 3 Hz spike wave pattern” as a marker for childhood absence and other idiopathic generalized epilepsies, “generalized 4–6 Hz polyspike wave/fast spike wave variant” in the context of juvenile myoclonic epilepsy (JME), “central temporal spikes” with benign epilepsy of childhood with central temporal spasms or West syndrome. It was recognized in early studies conducted on family members of probands with epilepsy that pure epileptiform abnormalities on the EEG could be inherited as genetic traits. Thus, the EEG plays an indispensable role in the investigation of epilepsy, by providing critical information and aiding in defining a “seizure type” and “syndromic” approach to epilepsy.

## 116.5 SEIZURE TYPES, EPILEPSY SYNDROMES

The International League Against Epilepsy (ILAE) has spearheaded efforts to provide a classification of seizure types and epilepsy syndromes (Table 116-1). The previously adopted classification is in the process of being revised. In the present chapter, we have used the proposed new terminology to try and use current nomenclature. Seizure types are broadly divided into (self-limited and continuous seizures) and further subdivided into focal/partial and generalized seizures. Details of seizure types and different epilepsy syndromes are available through the 2006 report of the ILAE classification core group (8).

Further attempts have been made to evolve and adapt current knowledge into the organization of epilepsies into electroclinical syndromes. Current recommendations use concepts of “genetic,” “structural–metabolic” and “unknown” to replace the terms previously used, i.e. “idiopathic,” “symptomatic,” and “cryptogenic.” Further, epilepsies are organized into distinct electroclinical syndromes, constellations (used to denote those entities that do not fulfill the concept of a syndrome, but

**TABLE 116-1 Proposed Seizure Classification (Task Force on Classification and Terminology)**

Comments	
<b>Generalized Seizures</b>	Generalized seizures are characterized by the appearance of a generalized bisynchronous epileptiform patterns (spike wave and/or sharp wave complexes) at a variable rate on the EEG, the clinical manifestations vary from negative phenomena such as motor arrest and unresponsiveness, to positive motor phenomena (tonic, clonic, tonic clonic, spasms, myoclonus)
Tonic clonic	
(in any combination)	
Absence	
* Typical	
* Atypical	
* Absence with special features	
Myoclonic absence	
Eyelid myoclonia	
Myoclonic	
* Myoclonic	
* Myoclonic atonic	
* Myoclonic tonic	
Clonic	
Tonic	
Atonic	
<b>Focal Seizures</b>	Focal or partial seizures exhibit a focal or regional epileptiform patterns of the EEG, with clinical manifestations dictated by the region of the brain that is the source, and the subsequent spread and activation of other brain areas that lie in the path of discharge.
	<b>Descriptors for focal seizures dependent on degree of impairment of consciousness</b>
	*Without impairment of consciousness/responsiveness
	+With observable motor or autonomic components (roughly corresponds to the concept of simple partial seizure)
	*Involving subjective sensory or psychic phenomena only (corresponds to the concept of aura)
	*With impairment of consciousness/responsiveness (roughly corresponds to the concept of complex partial seizure)
	*Evolving to a bilateral, convulsive seizure (involving tonic, clonic or tonic and clonic components; replaces the term secondarily generalized seizure)
<b>May be focal, generalized, or unclear</b>	
Epileptic spasms	

nonetheless are distinctive enough to be diagnostically meaningful and/or carry implications for treatment such as hypothalamic hamartoma associated with gelastic seizures, and Rasmussen's encephalitis), epilepsy with structural-metabolic causes, and epilepsy with unknown cause. These concepts are elaborated in detail in a special report of the ILAE Commission on Classification and Terminology 2005–2009; Table 116-2 (9).

## 116.6 GENETIC STUDIES IN HUMAN EPILEPSY

Support for the heritable basis to epilepsy is currently based on findings from (1) aggregation studies in families and twins, (2) linkage analysis and positional cloning of susceptibility genes, (3) association studies, and (4) study of single gene defects associated with human epilepsy, single gene defects in animal models of epilepsy (10).

A considerable volume of evidence comes from family- and population-based studies and has been extensively reviewed (10,11). There is a two- to four-fold increase in risk for epilepsy in patient families with a first-degree relative with epilepsy (12). Twins share similar environmental influences superimposed on either a monozygotic (MZ) or dizygotic (DZ) twin background. In childhood absence epilepsy (CAE) the high concordance rates in population-based studies of twins with epilepsy (for MZ versus DZ twins) provide strong supportive evidence for a genetic contribution (13). The application of contemporary ILAE classification schema to historical seizure data on twins collected by Lennox also provide evidence for a high concordance rate for idiopathic generalized epilepsies (MZ to DZ ratio (0.80 versus 0.00)) (14) (Table 116-3). Twin studies enable differentiation between the effects of shared genetic background and shared environmental influences. While population-based twin studies do offer investigators the ability to carefully phenotype individuals, twins may not necessarily be representative of the entire population. Such limitations involve problems of bias due to an excess of female MZ twins within volunteer registries.

Family-based studies of “multiplex families” are considered when several individuals within a single pedigree appear to be affected by the same epilepsy syndrome. Advances in molecular genetics have permitted the identification of mutations that account for specific epilepsy syndromes using carefully selected families. In the last two decades investigator groups have been successful in identifying several “epilepsy genes.” Using families with large numbers of affected individuals, using linkage analysis and positional cloning, gene loci were mapped and mutations affecting genes coding for different channel proteins identified. A closer look reveals that these are mostly “monogenic” epilepsies, i.e. these involve families showing a clear pattern of segregation consistent with Mendelian laws of inheritance. The concept of inherited epilepsy as a “channelopathy” took shape on the basis of these studies (15).

### 116.6.1 Monogenic Epilepsy

The majority of the causative mutations identified seem to affect ion- or ligand-gated channels with few exceptions. Mutations involving different gene loci may be expressed through a single phenotype (locus heterogeneity), while mutations involving the same gene may be expressed through completely different phenotypes at an individual level (variable expressivity). For example, the syndrome of generalized epilepsy with febrile seizures plus (GEFSP) is known to be extremely variable in its clinical expression, with multiple seizure type combinations associated with and without fever described in individuals within the same family. In GEFSP, mutations in 3 different genes are described; two sodium channel genes, *SCN1B* (16) and *SCN1A* (17), and a GABA receptor gene, *GABRG2* (18). In addition, at least 3 additional gene loci (2p24, 21q22, 8p23-p21) linked to this epilepsy phenotype have also been identified (19).

Mutations of *SCN1A* are also known to be causally associated with severe myoclonic epilepsy of infancy (SMEI). These are mostly de novo and truncating mutations (20), while the mutations leading to GEFS+ tend to be missense in type (21). Mutations of the *SCN1A* gene have also been identified in an expanding spectrum of epilepsy, including infantile epileptic encephalopathies (22) as well as cryptogenic generalized and focal epilepsy (23).

Mutations identified in the leucine rich, glioma inactivated 1 gene (*LGII*) have been found in 50% of families with two or more affected individuals with autosomal dominant partial epilepsy with auditory features (ADPEAF), however, in sporadic patients with the same clinical features, none were shown to carry an inherited mutation (24). Thus, the syndrome is dominant in some families; in others a “complex inheritance” is considered likely. These issues highlight the difficulties in fitting genetics of epilepsy into simpler schemes of Mendelian inheritance.

In addition to monogenic epilepsies above, nontraditional inheritance models also account for disorders with an inherited basis, where epilepsy is a prominent feature of the overall phenotype. These include imprinting disorders (differential expression of genes based on a parent of origin effect) (e.g. Angelman syndrome, mitochondrial inheritance) (e.g. myoclonic epilepsy with ragged red fibers, MERRF) and triplet repeat expansion (Dentatorubropallidoluysian atrophy, DRPLA) and dodecamer repeats (progressive myoclonic epilepsy). These have been extensively reviewed and discussed later (25).

### 116.6.2 Epilepsy with Complex Genetics

For geneticists, the former “idiopathic” epilepsy represents “epilepsy with complex genetics or complex epilepsy” i.e. multifactorial disorder with polygenic inheritance influenced by environmental factors as well as the internal milieu of the individual.

**TABLE 116-2 Proposed ILAE Classification of Epilepsy syndromes**

<b>Electroclinical Syndromes and Other Epilepsies</b>
Electroclinical Syndromes Arranged by Age at Onset*
Neonatal period
Benign familial neonatal seizures (BFNS)
Early myoclonic encephalopathy (EME)
Ohtahara syndrome
Infancy
Migrating partial seizures of infancy
West syndrome
Myoclonic epilepsy in infancy (MEI)
Benign infantile seizures
Benign familial infantile seizures
Dravet syndrome
Myoclonic encephalopathy in nonprogressive disorders
Childhood
Febrile seizures plus (FS+) (can start in infancy)
Early-onset benign childhood occipital epilepsy (Panayiotopoulos type)
Epilepsy with myoclonic atonic (previously astatic) seizures
Benign epilepsy with centrotemporal spikes (BECTS)
Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE)
Late-onset childhood occipital epilepsy (Gastaut type)
Epilepsy with myoclonic absences
Lennox–Gastaut syndrome
Epileptic encephalopathy with continuous spike and wave during sleep (CSWS) including:
Landau–Kleffner syndrome (LKS)
Childhood absence epilepsy
Adolescence–Adult
Juvenile absence epilepsy (JAE)
Juvenile myoclonic epilepsy (JME)
Epilepsy with generalized tonic-clonic seizures alone
Progressive myoclonus epilepsies (PME)
Autosomal dominant partial epilepsy with auditory features (ADPEAF)
Other familial temporal lobe epilepsies
Less Specific Age Relationship*
Familial focal epilepsy with variable foci (childhood to adult)
Reflex epilepsies
<b>Distinctive constellations</b>
Mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE with HS)
Rasmussen syndrome
Gelastics seizures with hypothalamic hamartoma
<b>Epilepsies attributed to and organized by structural-metabolic causes</b>
Malformations of cortical development (hemimegalencephaly, heterotopias, etc.)
Neurocutaneous syndromes (Tuberous sclerosis complex, Sturge–Weber, etc.)
Tumor
Infection
Trauma
Angioma
Peri-natal insults
Stroke
Etc.
<b>Epilepsies of unknown cause</b>
<b>Conditions with epileptic seizures that are traditionally not diagnosed as a form of epilepsy per se</b>
Benign neonatal seizures (BNS)
Febrile seizures (FS)

**TABLE 116-3** Concordance Rate for Epilepsy among MZ and DZ Twin Pairs

Study Authors	Nature of Epilepsy in Proband	Concordance Rates in Twins	
		Monozgotic <i>N</i> (%)	Dizygotic <i>N</i> (%)
Berkovic et al., 1998	Major epilepsy syndromes	108(62)	145(18)
Corey et al., 1991	Febrile seizures	95(19)	157(6)
Sillanpaa et al., 1991	Epilepsy	79(12)	201(3)

In “complex epilepsy” multiple susceptibility genes, and a triggering effect from the environment may be involved. There are no clear segregation patterns, and the phenomena of epistasis (intragenic interactions) influencing the gene expression are possible. Pleiotropic effects and epigenetic modification of expression also influence the final phenotype. The resulting phenotypic variability is such that stratification may be a problem.

Any discussion of epilepsy with complex genetics is linked to the nature of genetic variation and the role of natural selection in the occurrence of complex traits. A precise understanding of the nature of genetic variation in causation of epilepsy remains to be elucidated. Genetic variants linked to epilepsy could be common (allele frequencies >1%) or rare (allele frequencies <1%). The number and frequency of the susceptibility alleles are influenced by mutation, genetic drift and natural selection in the population. The common disease common variant model assumes that disease-causing variants have resisted natural selection to achieve a significant threshold within the population. This model has not found much support in terms of the identification of many common variants underlying human epilepsy, as association studies have failed to deliver consistent results (26). Another model, the common disease rare variant hypothesis (also called the multiple rare variant common disease model (MRVCE)) has been considered to be more applicable in the context of epilepsy. This model for complex epilepsy seems to involve causative variants in susceptibility genes drawn from a population of genes (with rare and low frequency polymorphic alleles) where none of the variants are sufficient in themselves to give rise to an epilepsy phenotype independently. The susceptibility alleles may give rise to the phenotype in different combinations, with each combination leading to a different endophenotype. As several single gene defects underlying monogenic epilepsy seem to code for proteins that make up ion- or ligand-gated channels, it would be natural to assume that variants in the genes coding for ion channels and their receptors would also be involved in complex epilepsy. Initial studies of variant polymorphisms with functional consequences—calcium channel subunits CACNA1H (CAE),  $\gamma$ -aminobutyric acid receptor subunits GABARD (GEFS+), and GABARB3 (idiopathic generalized epilepsy; IGE), potassium channel subunits KCND2 (TLE)—show themselves as carrying weak effects as far as their contribution to susceptibility to epilepsy is concerned. None of these variants have

been individually shown to have a causal association with genetic epilepsy (26,27).

From the foregoing discussion, both rare and common variant models for epilepsy individually are not broadly applicable to common epilepsy. To get around this problem a blended approach involving both the MRVCE (discussed above) and an ancestral common variant common epilepsy model has been suggested. In this polygenic heterogeneity model, the final expression of a disorder is determined by permutations and combinations of both common and low frequency polymorphic variants (26,28). With this background, it can be stated (at the risk of some oversimplification) that current thinking about genetic influences on the risk of epilepsy conceptually consist of the net effects resulting from a mix of “susceptibility genes with large effects” and those “with smaller effects,” the former producing Mendelian inheritance patterns, while the latter produce complex inheritance patterns. The detection and the construction of a composite of all genes with different contributions to determining susceptibility to epilepsy is the challenge for investigators. With the advent of high throughput technologies to study stable alterations in gene expression, contributions from structural variants in the genome (insertions, deletions duplications, inversions, and copy number variations) and nucleotide polymorphisms (SNP's) are seen to assume increasing importance in complex epilepsy.

### 116.6.3 Copy Number Variation in Epilepsy

Although a significant part of the human genome is conserved through evolution, even within these conserved regions, there are variations involving insertions and deletions of DNA ranging from 1 kb to several megabases constituting up to 12% of the human genome. Most of these variations termed copy number variants (CNV) are usually of no clinical significance (29); some, however, are considered as a source of mutations. CNV's can be detected by array specific comparative genomic hybridization (arrayCGH) and by SNP genotyping arrays (30). These technologies can be used to scan the entire human genome without any prior knowledge of the location of the “lesion.” CNVs can also be detected in targeted regions of the genome by the multiplex ligation-dependent probe amplification (MLPA) method. Previous studies have shown that CNV's are associated with many disorders with complex inheritance patterns

(intellectual disability, schizophrenia, and autism), and now have come under the scanner for complex genetically determined epilepsies (31). CNV's can be recurrent due to nonallelic homologous recombination in regions of segmental duplication. At least three microdeletions (15q11.2, 16p13.11 and 15q13.3) are now known to be associated with epilepsy; their combined frequency in populations with genetically generalized epilepsy is about 3%. The 15q13.3 microdeletion appears to be more specific for generalized epilepsy syndromes, whereas the other two have been described with both generalized and focal epilepsy syndromes (32). These larger recurrent CNVs appear to occur in rearrangement prone regions of the genome, hence detected more easily. The likelihood that rare nonrecurrent CNVs are also associated with epilepsy is a finding confirmed in recent studies (33). It has been suggested that the recurrent CNVs described above are providing an outline that encompasses a group of different electroclinical phenotypes within a "constellation" of genetic generalized epilepsies (childhood absence epilepsy, juvenile absence epilepsy, juvenile myoclonic epilepsy) syndromes.

## 116.7 MECHANISTIC DIVERSITY IN GENETIC EPILEPSY

The regulation of membrane excitability is a function of many types of gating channels. An ionic concentration gradient is maintained by all cells, with potassium being predominantly intracellular in its distribution, while sodium, chloride, and calcium are maintained at a higher extracellular concentration. These ionic gradients are maintained through the activity of ion channels that act as transmembrane pores, permitting rapid ionic fluxes to occur along electrochemical gradients. The ionic channels are capable of undergoing conformational changes, between an open and a closed state, enabling selective permeability to different ions, and to the direction of their flow under changing conditions. These processes are critical to electrical signal generation and transmission within the nervous system.

Ion channels are categorized as voltage-gated (their opening and closing depends on the electrical state of the neuronal membrane), or ligand-gated (the channel function is regulated by a ligand such as a neurotransmitter molecule, e.g. Ach or GABA, second messengers and metabolites). The location of these channels along the neuron, dendrites, and axons, presynaptic and postsynaptic processes is highly specialized. Regional differences in the distribution of ion channels, ligand-gated channels and signaling proteins, permits regional specialization of function. Structurally, these channels (Table 116-4) are formed by homomeric or heteromeric protein subunits coded by many different genes (34). Each ion- or ligand-gated channel is dependent on different families of subunits encoded by a multigene complex. The functional consequences of mutations in genes encoding

channel subunits can be variable. There may be a simple straightforward effect of either the loss of function or at other times a gain of function resulting in more complex effects on channel function and resultant seizure susceptibility. It is, however, important to point out that not all idiopathic epilepsies are channelopathies. A partial epilepsy syndrome (autosomal dominant lateral temporal epilepsy) is linked to a gene *LGII*, where the mutation involves a novel repeat motif coding for a leucine rich repeat protein, although the precise mechanism of how this links to epileptogenesis remains unknown. There are other examples for instance; mutations involving the *SLC2A1* gene that codes for a glucose transporter (GLUT1), that underlie early onset absence epilepsy, and the *EFHC1* gene mutations identified in juvenile myoclonic epilepsy point to the mechanistic diversity leading to seizure susceptibility.

### 116.7.1 Voltage-Gated Ion Channels and Epilepsy

**116.7.1.1 Loss of Function Mutations.** The identification of K channel mutations (KCNQ2, KCNQ3) associated with benign familial neonatal convulsions (BFNC) (35) preceded the recognition of Na channel (SCN2A) defects in the syndrome of benign familial neonatal-infantile seizures (BFNIS) (36). These findings provide irrefutable evidence linking ion channel dysfunction to epilepsy syndromes due to the loss of function effects of the pathogenic mutation. Voltage-gated potassium channels play a crucial role in neuronal physiology, involving post excitatory membrane repolarization by influencing M currents (K currents produced by activation of muscarinic receptors). When expressed in *Xenopus* oocytes, wild type KCNQ2 channels facilitate the development of M currents, while mutant channels show no such currents (37). By impairing the restoration of ionic balance after neuronal firing, potassium channel dysfunction likely leads to repetitive neuronal firing and a state of heightened excitability.

Sodium channel mutations also lead to a wide variety of neurological phenotypes, particularly within epilepsy syndromes including BFNIS, GEFS, and severe myoclonic epilepsy of infancy (Dravet syndrome). Sodium channels consist of an  $\alpha$  subunit (9 isoforms Nav1.1–Nav1.9) associated with two of four auxiliary  $\beta$ 1,  $\beta$ 2,  $\beta$ 3 and  $\beta$ 4 subunits in the CNS in a complementary fashion. The  $\alpha$  subunit contains the pore, whereas the associated  $\beta$  subunit determines the voltage dependency and other aspects of channel kinetics. There are four homologous domains (I–IV) and six transmembrane segments (S1–S6) forming  $\alpha$  subunits. A hairpin like P loop connects S5 and S6 forming a pore, while the intracellular loop connecting the domains III and IV forms the channel-inactivating gate (38). In the described mutations affecting BFNIS families, changes have been identified in the

**TABLE 116-4    Ion Channels: Structure and Subunit Composition**

<b>Ion Channel</b>	<b>Type</b>	<b>Associated Epilepsy</b>	<b>Composition</b>	<b>Mutations</b>	<b>Effect on Channel</b>
Sodium channel SCN1A/SCN2A SCN1B	Voltage-gated	GEFSP BFNIS SMEI	Each sodium channel is formed by 1 pore forming $\alpha$ -subunit and two $\beta$ -subunits that serve to modulate channel-gating kinetics. Each $\alpha$ -subunit is made from four tandem domains, each of which contains six transmembrane domains	SCN1B $\beta$ 1C121W SCN2A $\alpha$ 2L1330F $\alpha$ 2L1563V SCN1A Mutations are many and often occur de novo in the gene coding for this channel	Loss of function Slower
Potassium channel KCNQ2/KCNQ3	Voltage-gated	BFNC BFNC with myokymia	Each K channel is a tetramer made of four homologous subunits that contain six transmembrane domains. The fourth transmembrane domain carries amino acids that are positively charged which effects conformational change during depolarization. The pore-forming loop connects domains five and six	Multiple mutations described for KCNQ2	Loss of function Reduced current Both KCNQ2 and KCNQ3 are heteromultimers
Chloride channel	Voltage-gated	IGE	Chloride channels have two subunits each with its own pore	Three different mutations M200fsX231 IVS2-14del11, del 74-117 G715E	The first identified mutation in the $\text{ClC-1}$ gene
Nicotinic acetylcholine receptors CHRNA4/CHRNB2	Ligand-gated	NFLE	Pentamers with each subunit containing four transmembrane domains. In the human brain there are 10 subunits that can be expressed and may combine in heteromeric or homomeric combinations to form receptors. Relatively non selective channel	CHRNA4 $\alpha$ 4S248F $\alpha$ 4L776ins3 $\alpha$ 4S252L CHRNB2 B2V287L $\beta$ 2V287M	Gain of function Resulting in a nonfunctional receptor Mutations in the $\text{CHRNA4}$ gene
$\gamma$ -aminobutyric acid, subtype A GABRG2/GABRA1	Ligand-gated	GEFSP ADJME	Also shares a pentameric structure with four transmembrane domains Channel shows selective permeability to small anions and allows both chloride and bicarbonate	GABRG2 $\gamma$ 2K289M GABRA1 $\alpha$ 1A322D	Loss of function Mutations in the $\text{GABRG2}$ gene

$\alpha 2$  subunit of the sodium channel (SCN2A). Both the known mutations (L1330F, and L1563V) affect the highly conserved leucine, which results in an increased sodium current, which in turn reduces the rate of channel inactivation. SCN1A mutations have been described in association with GEFSP, Dravet syndrome and severe idiopathic generalized epilepsy of infancy (39). SCN1B mutations have been associated with GEFSP as well as a purely partial temporal lobe epilepsy phenotype (16,40).

**116.7.1.2 Gain of Function Mutations.** Activating mutations in inward rectifying potassium channels (KCNJ11) where a gain of function effect leads to a syndrome of developmental delay, neonatal diabetes, and epilepsy (41). Here the effects of heterozygous mutations in the *KCNJ11* gene result in the reduction of K(ATP) channel ATP sensitivity, increasing the K(ATP) current, which in turn inhibits beta-cell electrical activity and insulin secretion leading to diabetes, and in the brain paradoxically leads to increased excitability and epilepsy in the neonatal period. The condition can be ameliorated by the administration of a sulfonylurea that closes the potassium channel through an independent mechanism, particularly if the condition is recognized early (42).

The T type calcium channel is an obvious target channel as it plays a critical role in the thalamocortical oscillatory network. Missense mutations in a heterozygous state were identified in a gene coding for a calcium channel (CACN1H) in the 16p13 region in a small group of individuals with absence epilepsy, suggesting a role for calcium channels in the genetic susceptibility to absence epilepsy (43). The described mutations affect highly conserved regions in the T type calcium channel, functional studies using site-directed mutagenesis have shown a gain of function effect on calcium influx during physiological activation leaving the neuron vulnerable to repetitive firing (44).

**116.7.1.3 Ligand-Gated Ion Channels (Nicotinic Cholinergic Receptors, GABA Receptors).** The first evidence linking epilepsy to ion channel dysfunction came with the identification of a missense mutation ( $\alpha 4$ S248F) in the  $\alpha 4$  subunit of the nicotinic acetylcholine receptor (CHRNA4) in all 21 members of an Australian family affected by autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) (4). Different mutations in the *CHRNA4* gene (45), as well as in the gene coding for the *CHRNA2* ( $\beta 2$  subunit of the cholinergic receptor) have been identified in other families (46). The cholinergic receptor is a pentameric structure that is nonselective in its permeability to Na, K, and Ca. It appears that mutations directly affecting the channel pore can result in the epilepsy phenotype, as all of the known mutations appear to affect transmembrane domains that form the wall of the ion channel. Differences in the electrophysiological and pharmacological profiles among the different receptor mutations have been shown, such as increased cholinergic sensitivity, and reduced calcium permeability. It has been suggested that these differences

in mutant receptor function may account for additional specific phenotypic features such as the occurrence of neuropsychiatric symptoms (seen in individuals carrying the  $\alpha 4$ 776ins3 mutation) (47). In a family with individuals affected only with JME, a novel gene mutation (Ala322Asp) affecting the gene encoding for GABARA1 ( $\alpha$  subunit of the  $\gamma$ -aminobutyric acid receptor subtype A) has been identified. Voltage clamp recordings from HEK293 whole cell lines transfected with mutant and wild type GABA receptors show a reduction in GABA activated currents in the former. This observed effect is attributed to altered GABA receptor function, and not to reduced expression (48).

GABA receptor dysfunction can also be caused by mutations affecting other channels. Three different heterozygous mutations resulting in (1) a premature stop codon (M200fsX231), (2) an atypical splicing site (del74–117), and (3) an amino acid substitution (G715E), have been identified in the voltage-gated chloride channel gene (*CLCN2*) that co-segregate with other IGE traits in three families of 46 individuals selected for the study (49). Whole cell patch clamp recordings done after transfecting cell lines (tsA201 cells) with both mutant and wild type genes suggest an alteration of human *CLCN2* channel function, affected through different mechanisms. The end result is the induction of a hyperexcitable state at GABAergic synapses at a postsynaptic level. Altered GABA-related inhibitory influences underlie the IGE phenotype, despite the differing molecular targets of gene mutations.

In the above discussion, the results of pathogenic single gene mutations on seizure susceptibility are illustrated. A logical extension of this discussion is whether pathogenic variations in ion channel genes are enough to influence channel function in different ways serving to explain genetic risk of seizure susceptibility in complex epilepsy. In experimental work on a digenic animal model, which was generated carrying two mutations one in shaker K channel (*kcna1*), and another in calcium channel subunit (*cacn1a*) gene respectively had shown that while the mutations occurring singly served to enhance seizure susceptibility, the effect of carrying both mutations in the same animal model, however, resulted in a masking effect on the absence epilepsy associated with the calcium channel mutation (50). Such interactions between the effects of pathogenic genomic variants could potentially explain phenotypic variation seen within families in genetically complex epilepsy.

In summary, the genetic aspects of epileptogenesis seem to be characterized by involvement of multitude of genes, and other epigenetic processes involved in the regulation of gene expression. Ultimately, there is as a consequence of a change in the balance between excitability and inhibition in the nervous system and a defect in synaptic transmission. There is firm evidence for mechanistic diversity in the pathogenesis of idiopathic epilepsies. The pathways involve “channelopathy genes” as well as

other nonion channel genes. Several themes appear to emerge from the above discussion; firstly, that mutations in different genes may encode for subunits of the same channel, resulting in an epilepsy phenotype that is essentially related to the channel dysfunction in a nonspecific manner; secondly, mutations affecting different channels may result in the same phenotype, by net effects converging on a common pathway (convergent effect); and finally a situation where mutations affecting subunits of the same channel that may produce two entirely different epilepsy phenotypes (divergent effect).

## 116.7.2 Other Mechanisms (Channel Independent)

**116.7.2.1 Secretin Receptor Genes and Epilepsy Associated Repeats.** The identification of mutation in a G protein-coupled receptor underlying a murine audiogenic epilepsy phenotype (Frings and Frings mouse) led to the search for mutations in the human ortholog (*hMASS1*) (51). The gene was mapped to the 5q34 locus that exhibits linkage to febrile seizures (FEB4). Screening for mutations in the *hMASS1* gene in a family with this febrile seizure phenotype led to the identification of a nonsense mutation. Although the above mutation did not co-segregate with the febrile seizure phenotype in all families, it was suggested that a loss of function in this gene could lead to febrile and afebrile seizures (52). The genes *hMass1* and *VLGR1* appear to be two halves of a single gene now called MASSive G protein-coupled receptor 1 gene (*MGR1*) that belongs to a family of genes coding for secretin-coupled receptors (53).

In the rare ADPEAF, a gene mutation in the *LGII* gene was identified; this mutation also involves nonion channel genes. The structural aspects of the proteins coded by this and other genes (*VLGR1* on 5q14.1) and *TNEP1*(*C21LR* gene on 21q22.3) share a seven-fold repeated motif in the C terminal region that appears to define a superfamily of leucine-rich proteins termed EPTP which share seven bladed  $\beta$  propeller fold. The mechanisms through which these gene products influence epileptogenesis remain unclear at this stage (54).

JME is a genetic epilepsy syndrome where mutations in both ion channels and nonion channel genes have been found to play a causal role in some families. While GABARA1 mutation is described above, mutation in the gene *EFHC1* has been described in some Hispanic, Japanese and Italian families with JME. The gene codes for a conserved protein that is located in the choroid plexus is found in flagella, and motile cilia, mitotic spindles and appears to play a regulatory role in cell division. The deficiency of the same protein ortholog in mouse models is associated with a higher incidence of myoclonus and seizure susceptibility (55).

**116.7.2.2 Glucose Transporter Deficiency (Cerebral Energy Deficit).** A haploinsufficiency of the glucose transporter (*GLUT1*) caused by mutations in the gene

belonging to the solute carrier family (*SLC2A1*) underlies diverse group of neurological phenotypes from infantile epileptic encephalopathy, early-onset absence epilepsy to genetic generalized epilepsies, and movement disorders (56). The cerebral energy deficit within the nervous system characterized by a hypoglycorrachia leads to alteration in seizure threshold. The epileptic phenotype is often accompanied by generalized 2.5–4 Hz spike and wave complexes on the EEG (57).

**116.7.2.3 Somatic Mutations as a Cause of Sporadic Epilepsy.** Mutations occurring in somatic cell DNA acquired during brain development, or even in germ line DNA could potentially provide a pathogenic mechanism for certain kinds of sporadic epilepsies. An influence on tissue patterning may lead to the occurrence of two populations of cells; that either possess (or lack) the mutation. These mutational alterations may express themselves either through structural changes, or changes in receptor subunits within regions critical to epileptogenesis, eventually leading to epilepsy. This appears to be the case in some families with X-linked mental retardation associated with epilepsy (58). In a recent report of two Italian families with two sibs affected with SMEI, their parents were unaffected or had only experienced febrile seizures during childhood (59). In one family, DNA assays on parental lymphocytes demonstrated evidence of somatic mosaicism and in the other family there was evidence for germ line mosaicism in the mother.

## 116.7.3 Epigenetic Modification and Phenotypic Variability in Epilepsy

The biological explanation for the diversity of cellular proteins and their function lies in understanding the process of modulation and regulation of gene expression during cell development and proliferation. The rapidly expanding field of epigenetics (originally a term introduced by C. H. Waddington) (60) sheds new light on our understanding of phenotypic variability. Epigenetic processes in the form of DNA methylation, changes in nucleosome architecture and its regulation, regulatory non coding RNA's regulation and RNA editing, modifications to the histone proteins do not directly affect the genetic code; however, they modulate gene expression through changes in chromatin accessibility. DNA methylation and demethylation events are stable and are passed on during mitotic cell division. DNA methylation occurs at cytosines that reside as dinucleotide CpG-rich islands at the 5' end of regulatory regions. Through the addition of a methyl group to these cytosines, the gene is effectively silenced. Thus, methylation and demethylation processes effectively function as off-on switches for gene expression. Rett syndrome, a neurodegenerative disorder with significant epileptic seizures results from heterozygous mutations in the X-linked methyl CpG-binding protein 2 (*MeCP2*) gene. The *MeCP2* gene

product functions as a transcriptional repressor by binding to methylated DNA. The genetic deregulation that follows the occurrence of mutations in the X linked *MeCP2* genes, has been shown to affect the expression of genes (UBE-3 ligase and GABRB3) at other locations e.g. 15q11–q13 (Angelman syndrome) through possible histone modifications (61). Both Angelman and Rett syndrome share significant features of their clinical phenotype particularly in the occurrence of epileptic seizures. In addition to methylation, reversible posttranslational modifications of histone proteins are also involved in regulating gene expression. Histone modifying enzymes (histone deacetylases HDAC or histone acetylases HATs) as well as histone methyltransferases (HMTs or DNMTs) are involved in dynamic interactions with chromatin in determining whether the genes remain accessible for transcription (activation) or in a closed inaccessible state (silenced). Mutations in the *ATR-X* gene are responsible for  $\alpha$ -thalassemia mental retardation syndrome, a condition where 30% of patients are affected with epilepsy. These patients present with altered DNA methylation profiles and changes in chromatin architecture. *ATR-X* gene codes for a protein that interacts with a number of other epigenetic factors, including *MeCP2*, and is involved in diverse functions including transcriptional regulation, heterochromatin formation (62). *ATR-X* may mediate epileptogenesis through its activity in the maintenance, survival and differentiation of inhibitory interneurons thus altering the balance between excitation and inhibition (63).

Cellular methylation patterns are affected by changes in diet (availability of folate), hormone levels as well as inherited genetic polymorphisms (64). These aspects of epigenetics open up a Pandora's box of potential issues pertaining to the effects of dietary modifications. Inherited genetic polymorphisms (such as the C677T polymorphism) have been linked to elevated homocysteine levels following antiepileptic drug (AED) therapy as well as an increased risk of epilepsy in offspring born to Scottish women homozygous to the C677T susceptibility allele (65). The direct or indirect effects of the antiepileptic drugs on methylation patterns and epigenetic regulation remain to be better understood. Valproic acid (VPA) used commonly in long term epilepsy treatment has been of particular interest, as it actively enhances replication independent demethylation of DNA. VPA has been shown to block seizure-induced neurogenesis through its effect of HDACs (66). Its effectiveness thus may be linked to the prevention of aberrant neurogenesis that has been associated with the pathological consequences of status epilepticus. VPA and several other antiepileptic drugs are also folate antagonists and their effects of folate deficiency on methylation patterns remains to be fully understood. Nevertheless, one could speculate that these effects may have something to do with the teratogenic effects on fetal development as a consequence of pregnancy-related exposure. The reader desiring to learn

more about epigenetic processes that influence epileptogenesis is referred to this elegant review (67).

### 116.7.4 Modifier Genes

A role for modifier genes is in the final expression of an epilepsy phenotype that could contribute to the observed variability in phenotypic expression within a defined epilepsy syndrome as observed in the GEFSP and in SMEI (68).

In a mouse model of GEFSP carrying the *scn1a* mutation, mutant alleles carrying coding and noncoding variants in sodium (*scn1a*, *scn2a*) and potassium channels (*kcnq2*) have been shown to have a deleterious effect on seizure severity, while the presence of a mutant (*scn8a*) allele restores normal seizure threshold, as well as prolonging survival of these GEFSP mutant mice (68). Evidence from studies of mouse models carrying ion channel mutation strongly suggest that the explanation underlying phenotypic variability encountered within families carrying for instance a *SCN1A* mutation may be influenced by genetic modifiers, stochastic events during development, epigenetic and environmental influences. So in the future, genetic assessments of risk for epilepsy as well as for guiding treatments, molecular work up of patients will need to focus on a whole panel of ion channel genes than a single affected gene, and will have to take into account the influence of variants in the coding and noncoding regions and other modifier genes.

The gene mutations so far described result in altered channel characteristics through loss or gain of function. Among the nonion channel genes, mutations appear to affect proteins that share structural similarities (seven-fold repeat motifs in the LGI family of proteins), leading to the speculation of a final common pathway that may or may not necessarily be linked to ion channels. The finding of involvement of a glucose transporter protein, and the *SLC2A* gene in association with the genetically generalized epilepsies, provides yet another example of the diverse mechanisms underlying genetic aspects of human epilepsy. The challenge of breaking out of the channelopathy paradigm is already bearing results given the expanding research interests into a genotype first approach using current high throughput technologies to study variation within the entire genome in populations with epilepsy. Such a genotype-first approach accompanied by a careful search for rare variants within the phenotype or constellation of genetic generalized epilepsies will lead to a knowledge base where one may begin to build a classification of epilepsies based on the recognition of the molecular genetic basis. Such diagnostic testing should be possible through the availability of next generation high throughput exome sequencing technologies. Combined with this will be an ever-greater need for powerful bioinformatics as there will be enormous data generated, to sift through and understand what is truly a significant result.

## 116.8 SELECTED GENETIC EPILEPSY SYNDROMES

For the purpose of discussion, we have grouped disorders on the basis of age of onset and recognized electroclinical syndromes. The symptomatic epilepsies with a genetic basis present a challenge to categorize, as there is too much variability in seizure phenotype. Details of clinical descriptions are considered in brief or provided in several tables. (Table 116-5) The following discussion focuses on the gene defects identified and implications for the epilepsy phenotype.

### 116.8.1 Genetic Generalized and Focal Epilepsy syndromes

**116.8.1.1 Neonatal Period and Infancy.** At least two distinct electroclinical syndromes with Mendelian inheritance pattern have been identified, with seizures that begin in the neonatal period and infancy. The syndromes are characterized by an age-dependent onset of epileptic seizures, a relatively benign outcome in the majority, and at a molecular level are related to a pathogenic mutation in an ion channel. The seizure semiology in these syndromes is described in Table 116-5.

**116.8.1.1.1 Benign Familial Neonatal Epilepsy.** Mutations involving genes coding for a family of voltage-gated potassium channels (KCNQ) that play a critical role in the repolarization of neurons underlie this form of epilepsy (35,69). The reason why a fixed genetic deficit in potassium channel structure should lead only to intermittent seizures that tend to remit over time in early life may be related to changing spatial and temporal patterns of expression of potassium channel subunits during brain development (70). The possibility that this effect could also be mediated by genetic modifiers is also entertained.

**116.8.1.1.2 Benign Familial Neonatal-Infantile Seizures.** The seizures in this condition are of later onset around 3 months of age and seizures almost always remit by age 12 months. A mutation in  $\alpha 2$  subunit of the voltage-gated sodium channel (SCN2A) has been identified in individuals in an Australian family and in a family previously described by Lewis et al. (36). The clinical seizure phenotype has been named BFNIS, adding another seizure susceptibility syndrome to epilepsies beginning in early life. The mutations described are all missense and predicted to be associated with a gain of function, however recently three of the described mutations were found to be associated with a loss of function (71).

**116.8.1.2 Febrile Seizures and Related Syndromes.** Febrile seizures and other idiopathic epilepsies strongly related to the febrile seizure phenotype at presentation are discussed together (Table 116-6).

**116.8.1.2.1 Febrile Seizures.** Febrile seizures (FS) are classified as “situation-related” (72); they affect 2–5% (Europe) and 6–9% (Japan) of children in between

the ages of about 6 months and 5 years. FS are associated with a low risk of subsequent epilepsy, although a few children with FS, especially with the complex type, will develop temporal lobe epilepsy later in life (73).

The genetic basis for FS is considered likely, based on their increased occurrence in families. In particular, twin studies have demonstrated a much higher risk in MZ than in DZ twins (40% versus 7%) (74). A complex polygenic inheritance pattern is currently favored. At least six susceptibility loci have been mapped, although the causative genes have not been identified in most patients: FEB1 (8q13–q21), FEB2 (19p13), FEB3 (2q23–q24), FEB4 (5q14–q15), FEB5 (6q22–q24), and FEB6 (18p11). The FEB4 locus was also confirmed in nuclear families and may account for 70% of commonly encountered febrile seizure susceptibility. The FEB3 locus at 2q23 was reported in large Utah family, and the seizure descriptions are considered to be close to GEFSP, so this may be considered more as a GEFSP locus (75).

#### 116.8.1.3 Epileptic Encephalopathy of the Neonate and Infant.

**116.8.1.3.1 Ohtahara Syndrome.** The condition is associated with a progressive epileptic encephalopathy beginning in the first 2 months of life, severe seizures, and a characteristic suppression burst pattern on the EEG. While most infants with this condition have structural brain abnormalities demonstrable on neuroimaging, presently the syndrome appears to be associated with both genetic and metabolic etiologies. Pathogenic mutations in the Aristaless homeobox gene (ARX) (X linked infantile spasms), syntaxin binding protein (STXBP1) (76), and mitochondrial respiratory chain defects have been found causative (77). A pathogenic mutation in a mitochondrial glutamate transport carrier SLC25A22 has also been described in association with features of Ohtahara syndrome in an Arab-Israeli family with multiple affected individuals (78). Many of these patients transit into West syndrome in an age-dependent manner. It should be noted that STXBP1 mutations are also reported in an early-onset epileptic encephalopathy that did not clearly meet the criteria for the diagnosis of neither Ohtahara syndrome nor West syndrome (79).

**116.8.1.3.2 Infantile Spasms/West syndrome.** The diagnosis of West syndrome is based on the occurrence of characteristic seizure type (axial epileptic spasms), EEG findings of hypsarrhythmia, developmental arrest eventually leading to psychomotor retardation. While in a substantial proportion of infants diagnosed with infantile spasms are attributable to structural metabolic causes with a genetic basis, in a small proportion of cases genetic mutations have been identified in the “idiopathic/cryptogenic” cases. These mutations involve the X linked ARX gene, cyclin dependent kinase like-5 (CDKL5/ serine-threonine kinase 9) and syntaxin binding protein (STXBP1) and phospholipase C beta1 deficiency (76a,80). Mutations in these genes are associated with not only West syndrome, but also with

**TABLE 116-5 Electroclinical Syndromes by Age of Onset**

Epilepsy Type	Type of Seizure	Clinical and EEG Characteristics	Chromosomal Locus and Mode of Inheritance	Molecular Defect
Benign familial neonatal epilepsy	Unilateral or bilateral clonic, tonic clonic, apneic, and tonic seizures	Interictal EEG is normal, seizures are brief, on day 2 or 3 of life, recurrent, 15% may develop epilepsy in later life	Autosomal dominant 20q	Mutation in voltage-gated K channel genes (KCNQ2,KCNQ3)
Benign familial neonatal–infantile seizures (BFN-IS) MIM #607745	Mixed seizures similar to BFNC	Age of onset between 2 and 7 months, remit in the first year	Autosomal dominant 2q	Mutations in the $\alpha 2$ sub-unit of Sodium channel (SCN2A) gene
Benign familial infantile convulsions (BFIC1) MIM %601764	SPS CPS	Age of onset 4–8 months Parieto–occipital foci Remit by age 3 years	Autosomal dominant 19q11–13 in Italian families is also associated with another gene locus 16p12–q12	Causative gene remains unknown
Early infantile epileptic encephalopathy (Ohtahara)	Intractable tonic spasms Progressive Encephalopathy	Seizure onset in the first month, suppression-burst pattern on EEG Evolution to West syndrome and Lennox–Gastaut syndrome Often structural brain abnormalities seen	Sporadic forms	Mutations in <i>STXBP1</i> (syntaxin binding protein 1 gene) and <i>ARX</i> gene have been identified in sporadic patients with Ohtahara syndrome
X linked infantile spasms in boys	Epileptic spasms Flexor, extensor, mixed Psychomotor retardation	EEG shows hypsarrhythmia Progressive MR Male patients with MR, intractable epilepsy Rett like features in females	Recessive and dominant X linked forms identified	Recessive forms <i>ARX</i> gene mutations Dominant <i>CDKL5</i>
Epilepsy with mental retardation X linked	Seizure types include GTCS, myoclonic and tonic seizures, absences, and focal seizures	Seizures start from the age of 6–36 months and may be precipitated by fever	X linked	Mutations in the Protocadherin ( <i>PCDH19</i> ) gene
Generalized epilepsy with febrile seizures plus (GEFSP)	Febrile Afebrile seizures GTCS FS + Absences, myoclonic seizures Atonic seizures	FS extend beyond age 6 and accompanied by other seizure types Good AED response Normal interictal EEG	Autosomal dominant 50–60% penetrance	Mutations in <i>SCN1A</i> (5-10%), <i>SCN1B</i> (4.1%) and <i>GABRG2</i> genes <1%) All GEFSP mutations are missense
Dravet syndrome	Febrile hemiconvulsions in the first year	Mixture of intractable generalized (myoclonic or atonic seizures, atypical absences) and focal seizures, normal early development, Subsequent psychomotor retardation, and normal brain imaging at onset Interictal EEGs are initially normal but progressively show generalized spike-and-waves, polyspike-and-waves, focal abnormalities, and photosensitivity	Sporadic Denovo	Mutations in the <i>SCN1A</i> gene in 32–100% of patients Truncation Missense

**TABLE 116-6 Idiopathic/Genetic Generalized Epilepsy Syndromes**

Epilepsy Type	Type of Seizure	Clinical and EEG Characteristics	Chromosomal Locus and Mode of Inheritance	Gene Testing (Availability, Accuracy, Utility)
Idiopathic Generalized Epilepsy (IGE) MIM 600669	GTCS Absence Myoclonic	Normal intellectual development Age of onset and seizure type differ in different syndromes Generalized 3 Hz or faster spike, polyspike and wave complexes	Complex Polygenic 3q26 SLC2A1 mutations in 10% of early onset absence	Limited only for (SLC2A1) Accurate Implications for treatment and counseling
Childhood Absence Juvenile Absence Juvenile Myoclonic Epilepsy with grand mal on awakening				
Familial juvenile myoclonic epilepsy	GTCS Absence Myoclonic	Only pure JME in all affected individuals Age of onset 8–25 years. Diffuse polyspike–multispikes waves (3.5–6 Hz)	Autosomal dominant 5q34	No Not useful

Familial febrile seizures (FS) FEB1 MIM %602476 FEB2 MIM %602477 FEB4 MIM %604352	Generalized seizures	6 months–5 years Typical febrile convulsions	Genetic heterogeneity 8q13 (FEB1) 19p13 (FEB2) 5q14 (FEB4)	NA

other early onset epileptic encephalopathies as discussed above (76a,80,81). Of these three genes, *ARX* gene mutations exhibit remarkable phenotypic variability and pleiotropy: protein truncation mutations are associated with malformation phenotypes while missense mutations are associated with nonmalformation phenotypes. X-linked infantile spasms, are associated with missense mutations outside of the homeobox and expansion of the polyA tracts (82). Pathogenic mutations in the gene *SPTAN1* coding for  $\alpha$ -II spectrin has been reported in association with early-onset West syndrome associated with cerebral hypomyelination, visual symptoms, and developmental delay (83), adding to the panel of genes that will need to be screened for in cases of West syndrome where a genetic basis is suspected.

#### 116.8.1.4 Childhood Onset Epilepsy Syndromes.

**116.8.1.4.1 Generalized Epilepsy Febrile Seizures Plus.** The seizure phenotype in febrile seizures plus includes the persistence of febrile seizures beyond age 6 years or association with occurrence of afebrile seizures. Very often these seizures are generalized (tonic-clonic, myoclonic, atonic, or absence) seizures, however, focal seizures of frontal, temporal origin are also recognized (17b,84). The mode of inheritance in GEFS plus remains a matter of debate; in some a dominant pattern, in others an oligogenic effect is thought to account for the wide variation in clinical phenotype. So far the gene defects identified appear to involve subunits of voltage-gated sodium channels (17a), and subunits of the ligand-gated GABAergic receptors (18,85). Both types of mutations appear to affect the functional properties of the respective channels,

and may serve to enhance seizure susceptibility in a non-specific manner. The familial *SCN1A* mutations identified to date have all turned out to be missense in type (86).

**116.8.1.4.2 Severe Myoclonic Epilepsy (Dravet syndrome) and Other Epileptic Encephalopathies.** The phenotype in SMEI represents the severe end of the spectrum of the epilepsies encountered with *SCN1A* mutations. Prolonged unilateral clonic or hemiconvulsive febrile seizures at onset in the first year of life in developmentally normal children, progress to intractable afebrile seizures (atypical absence, myoclonic and partial seizures). Intractable epilepsy is accompanied by ataxia and the development of pyramidal signs. The interictal EEG shows bihemispheric generalized spike waved discharges, which can be asymmetrically expressed. Imaging studies fail to show structural abnormalities in the brain. There is often developmental regression and a long-term unfavorable outcome. About 400 mutations considered to be pathogenic have now been identified and described in the sodium channel gene *SCN1A*. The majority appears to be arising de novo. Missense (40%) and truncating mutations (50%) in the *SCN1A* gene (coding for the  $\alpha$  1 subunit for the sodium channel) constitute a majority of the known mutations associated with SMEI (20b,87). There is evidence to suggest that such de novo mutations may be of paternal origin, as the mutational events have a greater chance during mitoses occurring during spermatogenesis (88). There is considerable overlap with GEFS, where similar mutations have been described (89). The phenotypic variability of epilepsy phenotypes associated with sodium channel mutation has expanded

considerably with the description of patients with borderline severe myoclonic epilepsy (SMEB), with intractable epilepsy lacking specific features of SMEI, as well as reports of intractable childhood epilepsy with generalized tonic clonic seizures, infantile spasms, Lennox–Gastaut syndrome (22), atypical Panayiotopoulos syndrome (90), and Rasmussen’s encephalitis (91). An added mutational mechanism in SMEI has been the finding on novel copy number variants as duplications/deletions in SCN1A detected by multiplex ligation-dependent probe amplification (MLPA) and characterized further by arrayCGH in patients where initially no mutations were identified (92). Finally the discovery of SCN1A mutations in a substantial number of patients with vaccine associated encephalopathy adds yet another neurological phenotype, unmasked by administration of vaccine.

**116.8.1.4.3 Glucose Transporter 1 Deficiency Syndrome.** An infantile seizure disorder associated with hypoglycorrhachia was attributed to a defective glucose transport carrier across the blood–brain barrier was first reported in 1991 (93). Haploinsufficiency or hemizygosity of the GLUT1 transport carrier was identified as the cause (56a), with both sporadic de novo occurrence and autosomal dominant inheritance patterns identified (94). The condition can also be transmitted as an autosomal recessive in rare instances (95). The phenotype of the epilepsy syndrome associated with this condition has rapidly expanded to include both a severe form of an epileptic encephalopathy presenting with infantile seizures to milder intermittent symptoms that can range from paroxysmal movement disorders, intermittent seizures (56c). All seizure types (generalized tonic or clonic, myoclonic, atypical absence, atonic, and unclassified) are reported. Mutational hotspots in the gene coding for a solute transporter (*SLC2A1* gene) have been identified leading to a defective GLUT1 transport protein. The recognition of this condition is particularly important as the severity of the condition ameliorated and symptoms controlled by the administration of the ketogenic diet. An added discovery that up to 10% of patients with early-onset absence epilepsy as well as other types of genetic generalized epilepsies carry milder mutations in the *SLC2A* gene assumes great clinical importance as these cases are indistinguishable from other absence epilepsies. Further GLUT1 deficiency may be more amenable to treatment with the ketogenic diet in addition to the implications for genetic counseling.

#### **116.8.1.4.4 IGE Syndromes.**

**116.8.1.4.4.1 Childhood and Juvenile Absence Epilepsy, Juvenile Myoclonic Epilepsy, Epilepsy with Grand Mal on Awakening.** The clinical and EEG features of IGEs show considerable overlap. Seizure types include absence, tonic, tonic–clonic, clonic, or myoclonic seizures, the interictal EEG shows bursts of synchronous generalized epileptiform patterns over both cerebral hemispheres and a normal background. In each syndrome, there is an age-dependent onset of a particular

seizure type. Affected individuals are of normal intelligence, the neurological examination is usually normal. (Table 116-6).

Mutations hitherto identified in molecular studies appear to affect different targets that include a GABA receptor subunit (GABARA1) in JME (48), a chloride channel (CLCN2) in IGE (49), and a calcium channel (CACNA1H) in CAE (43). The mutations appear to carry a net effect on altered GABAergic function and altered patterns of synchronized burst firing within thalamocortical circuits (48,49).

**116.8.1.4.5 Idiopathic Partial Epilepsies.** Most partial or focal epilepsies were assumed not to have a genetic basis. Relatives of probands with partial epilepsy have an increased risk of epilepsy compared to the general population, suggesting a genetic influence in at least some forms of partial epilepsy. In order for partial seizures to be caused by a gene defect, the defective gene either has to cause localized cortical hyperexcitability, or has to be expressed only in certain neuronal regions, or its effects are modified by local factors (96). The partial epilepsy syndromes and the chromosomal loci to which they are mapped are summarized in Table 116-7.

**116.8.1.4.5.1 Nocturnal Frontal Lobe Epilepsy.** ADNFLE is transmitted in an autosomal dominant fashion with incomplete penetrance, thus displaying intra-familial variability in clinical expression. Cholinergic receptor mutations have been shown to underlie this epilepsy phenotype and have been discussed at length earlier.

**116.8.1.4.5.2 Familial Temporal Lobe Epilepsy and Other Partial Epilepsies.** Ottman et al. described a single family of 11 affected individuals who presented with partial seizures beginning during adolescence, and nonspecific auditory disturbances (97). The condition is now recognized by the term ADPEAF or autosomal dominant lateral temporal lobe epilepsy. Sequencing all the 28 genes in the implicated 10q24 locus, mutations were identified in the leucine rich glioma inactivated 1 gene (*LGI1*) (24a).

Other autosomal dominant inheritance patterns for partial epilepsies have been identified in clinical studies of large families: autosomal dominant partial epilepsy with variable foci (98), autosomal dominant rolandic epilepsy with speech dyspraxia (99) and benign familial infantile convulsions (BFIC) (100). While linkage studies have suggested associated loci, however so far, a mutation has not been identified.

**116.8.1.4.5.3 Benign Epilepsy of Childhood with Central-Temporal Spikes.** A strong genetic influence in benign rolandic epilepsy has been an early consideration (101). The epilepsy syndrome appears to be inherited as autosomal dominant with age dependent penetrance and the EEG trait is inherited similarly (102). There is an increased incidence of both focal and generalized EEG abnormalities among first-degree relatives. (Interestingly, in relatives generalized abnormalities are even

**TABLE 116-7 Genetic partial epilepsy syndromes**

Epilepsy Type	Type of Seizure	Clinical and EEG Characteristics	Chromosomal Locus and Mode of Inheritance	Gene Testing Availability Accuracy Utility
Nocturnal frontal lobe epilepsy (ENFL1, 2, 3) MIM #600513	SPS	Age of onset 8 y Nocturnal seizures, occur in clusters with aura Frontal lobe origin Tonic, hyperkinetic movements often mistaken for sleep disturbance	Autosomal dominant 20q13.2–13.3 15q24 1q	Yes Accurate Useful Establishes etiology Genetic counseling implications
Familial lateral temporal lobe epilepsy with auditory features (ADPEAF) MIM#600512	SPS	Childhood or adolescent onset Partial seizures Acoustic and visual hallucinations Aphasia Seizure precipitation by speech activation Vertigo	Autosomal dominant Genetic heterogeneity 10q22	Yes Accurate Not very useful
Familial Partial Epilepsy with variable foci MIM %604364	SP, CPS and SGTC	Age of onset 8–10 years Migrating spike foci Frontal, temporal Normal intelligence	Autosomal dominant 22q11–q12

more common than focal ones). Linkage to 15q13 locus has been demonstrated in family studies (103).

### 116.8.2 Progressive Myoclonic Epilepsy Syndromes

Progressive myoclonic epilepsies share in common the phenotypic features of myoclonic and generalized seizures, and progressive cognitive decline and ataxia. (Table 116-8). The differential diagnosis is wide and include many genetic conditions such as phakomatoses, inborn errors of metabolism, storage disorders, chromosomal abnormalities, mitochondrial disorders, neurodegenerative disorders (ceroid lipofuscinoses), Unverricht Lundborg (Baltic myoclonus) syndrome (cystatin B gene), Action myoclonus renal failure syndrome (SCARB2). Newer genes are being identified, where pathogenic mutations are associated with progressive myoclonic epilepsy (SCARB2 mutations in PME without renal failure, PRICKLE1 mutation in recessive PME with ataxia) (104). These disorders involve both Mendelian and non-Mendelian inheritance patterns and provide a paradigm for a common phenotypic expression for multiple defects at a molecular level resulting in myoclonic seizures. Selected conditions are discussed later, and the problem of progressive myoclonic epilepsies is reviewed in greater details elsewhere (105).

**116.8.2.1 Unverricht Lundborg syndrome.** EPM1 has been mostly reported in a genetically homogeneous population. The gene CST6 at the 21q22.3 locus codes for a protein called cystatin B (CSTB), a cystine protease

inhibitor. Cystatin B mRNA was found to be markedly reduced in EPM1 patients. Point mutations have also been described in the CST6 gene, accounting for 10% of EPM1 alleles, while in the most common EPM1 Baltic/Finnish or Mediterranean haplotypes, no point mutations were found. In the latter, a polymorphic unstable dodecamer repeat expansion (CCCCGCCCGCG) *n* located 174 nucleotides upstream of the initiation ATG codon of CSTB in the promoter region of the CST6 gene, was demonstrated (106). The condition may be under diagnosed in patients with drug resistant myoclonic epilepsy (107).

The process by which changes in the promoter region result in reduction in CSTB transcription remains unknown. The expansion is different from the triplet repeat expansion, but several lines of evidence suggest moderate intergenerational instability particularly with male transmission (106d). There is no relationship between the size of the repeat expansion and the age of onset of the disease. As a ubiquitous protease inhibitor, CSTB is speculated to play a critical role in the maintenance of neuronal integrity. Neuronal degeneration particularly of the cerebellar granule cells is noted in the knock out mouse models, with epilepsy being a secondary effect (108). In a human postmortem study evidence of neuronal degeneration, neuronal cytoplasmic inclusions containing the lysosomal proteins, Cathepsin-B and CD68, as well as immunoreactive intranuclear inclusions were prominent suggesting that neuronal degeneration in at least is in part mediated by deficient cystatin mediated neuroprotection (109).

**TABLE 116-8 Progressive Myoclonic Epilepsies (EPM)**

Epilepsy Type	Type of Seizure	Clinical and EEG Characteristics	Chromosomal Locus and Mode of Inheritance	Molecular Testing
Progressive myoclonic epilepsy of Unverricht Lundborg (EPM1) #MIM 254800	GTCS Myoclonic	Seizures begin early, with mental deterioration, ataxia a late feature Photosensitive myoclonus Spike wave discharges precede seizures	Autosomal recessive 21q22.3	Targeted mutation analysis Sequence Analysis Clinical testing available for mutations in cystatin B gene

Gene testing and relevant information on molecular diagnostic test, and laboratories performing such testing is accessible through the NCBI website. <http://www.ncbi.nlm.nih.gov/sites/GeneTests/lab?db=GeneTests>

### 116.8.2.2 Dentatorubral–Pallidoluysian Atrophy.

DRPLA is a disorder caused by expansion of trinucleotide repeats (CAG, >49 repeats) within a gene of unknown function (110). DRPLA exhibits genetic anticipation, variable penetrance, and heterogeneity. The gene codes for polyglutamine tracts and the defective protein has been termed “atrophin.” Attention has focused on the interaction of these polyglutamine tracts with other

intranuclear proteins that function as transcription factors (TATA, CREB and CREB binding proteins) (111). Progressive neuronal impairment is thought to result from irregularities in transcription induced by abnormal protein–protein interactions (112).

### 116.8.2.3 Myoclonic Epilepsy of Lafora/Lafora disease.

Progressive myoclonus epilepsy of the Lafora type (EPM2/MELF) presents during late childhood or

adolescence has a fatal outcome that is inevitable within a decade of the onset of initial symptoms. Periodic acid-Schiff (PAS) positive cytoplasmic inclusion bodies are identified intracellularly within neurons, skeletal muscle, hepatocytes, and sweat glands in the skin and are considered diagnostic. The inclusions (Lafora body) are composed of a starch-like substance termed polyglucosans and are identified within eccrine glands and in the myoepithelial cells surrounding apocrine glands of the skin (113). There is a cautionary note in that the cells of the apocrine gland itself may show PAS+ granules giving rise to a false positive result (114). Therefore, many centers prefer biopsy sites outside of the axilla where generally apocrine glands are absent. More recently it has been shown that skin biopsies can have a high negative rate even in classical form of Lafora disease (LD), where mutational analysis can confirm the presence of a pathogenic mutation.

The inheritance pattern for this disorder is autosomal recessive with genetic heterogeneity (2 loci *EPM2A*, *EPM2B*). The *EPM2A* gene codes for a gene product laforin, a dual function tyrosine phosphatase, which exists in two isoforms (cytoplasmic, ER, and nuclear) (115). Mutations affecting laforin appear to involve the cytoplasmic isoform. The *EPM2B* locus on DNA sequencing and screening leads to the identification of gene *NHLRC1* (NHL repeat containing gene 1) carrying a pathogenic mutation. Several mutations have now been identified in this gene in different families with EPM. The *NHLRC1* codes for malin, a 395 amino acid protein with a putative E3 ubiquitin ligase function that is predicted by the presence of zinc-binding RING finger domain (116). Both gene products appear to localize at the ER and may be involved in clearance of polyglucosans. It is suggested that the disorder arises through the accumulation of polyglucosans within neuronal dendrites and the resulting disturbance in synaptic function gives rise to increased seizure susceptibility in the nervous system (117). Further work in animal models has suggested that glycogen hyperphosphorylation is the principal biochemical abnormality in LD (118). Excess glycogen phosphate further leads to glycogen conformational change, unfolding, precipitation, and conversion to polyglucosan (119).

**116.8.2.4 Myoclonic Epilepsy with Ragged Red Fibers.** The disorder derives its name from the histopathological appearance of “ragged red muscle fibers” resulting from the subsarcolemmal accumulation of mitochondria, seen in muscle sections stained by the trichrome stain. Three mutations (A8344G, T8356C and G8363A), in the human mitochondrial DNA (mtDNA) affecting the tRNA (*Lys*) gene have been identified in the majority of patients with MERRF (120). The resulting defects in complex I and IV enzymes of the oxidative-phosphorylation system (121) are responsible for an energy deficit within affected cells carrying abnormal mitochondrial population above a certain threshold. The proportion of normal and mutant mitochondrial DNAs in affected tissues at a

particular age may be one of the factors determining the severity of symptoms. Currently, it is believed that the pathogenic tRNA mutations lack a posttranscriptional taurine-modification at the anticodon wobble uridine that leads to defective translation of either of its codons (AAA and AAG) and it is this inability that underlies the molecular pathogenesis of MERRF (122).

**116.8.2.5 Lysosomal Storage Disorders.** Sialidosis, neuronal ceroid lipofuscinosis (NCL) and GM2 gangliosidosis are autosomal recessive neurometabolic storage disorders in which characteristic inclusion bodies or storage material are identified within neurons, resulting in their degeneration. In these disorders, myoclonic seizures likely occur as a secondary phenomenon.

Sialidosis results from a mutation in the gene encoding glycoprotein specific  $\alpha$ -neuraminidase. Neuraminidase cleaves terminal sialic acid residues from sialoglycoconjugates, and deficiency of the enzyme results in accumulation of these conjugates within the cell (115a). The NCL present with a combination of seizures (with the exception of CLN1), psychomotor decline, and visual failure with varying age of presentation. The age of onset, clinical features, and the ultrastructural appearance of the intracellular lipopigment accumulations form the basis of division into subtypes. At least eight mutant genes (*CLN1*–*CLN8*) are suspected, while six gene loci have been mapped, with the exception of *CLN4* and *CLN7*. With the exception of the protein encoded by the gene *CLN1*, lysosomal accumulation of mitochondrial ATP synthase subunit “c” forms a substantial part of the inclusions in the remaining subtypes. The proteins defective in *CLN1* (123), and *CLN2* (124) are lysosomal enzymes, that are mannose 6-phosphate dependent for their trafficking and have a role in protein degradation. The remaining proteins associated with *CLN3* (125), *CLN5* (126) and *CLN6* are predicted to function as transmembrane proteins, while it is shown that *CLN8* protein is localized to the ER/Golgi apparatus.

Thus, impaired lysosomal degradation and trafficking of proteins may be the common theme underlying this group of disorders with overlapping clinical features. It is clear that CLN proteins are critical to the nervous system, as it bears the brunt of the damage in these disorders, even though the storage product is found in tissues outside the nervous system. It has been suggested the machinery for synaptic functioning bears similarities to the machinery involved in lysosomal protein trafficking. Impaired synaptic function may be the final common endpoint of enzymatic/genetic defects in the NCL group of disorders (127).

### 116.8.3 Genetic Epilepsy Associated with Structural Causes

Abnormal cortical development can result in a predilection for seizures, in addition to encephalopathy, developmental delay, and motor problems in early life. Disorders

of neuronal migration account for nearly 25% of recurrent childhood epilepsy. Studies of surgically resected specimens from patients with intractable seizures show a 30–50% incidence of developmental malformations, especially in children (128). Many single gene defects that lead to malformations of cortical development are now known that include tuberous sclerosis, lissencephaly, and periventricular nodular heterotopia (Table 116-9). These genes are involved in the regulation of intracellular signaling, as well as protein–protein interactions that control neuronal growth, differentiation, and migration.

**116.8.3.1 Tuberous Sclerosis.** The *TSC1* gene, on chromosome 9q34, encodes a widely expressed protein (hamartin) that is postulated to function as a tumor-suppressor gene (129). The *TSC2* gene, on chromosome 16p13.3, encodes a protein product (tuberin) (130). Tuberin and hamartin associate with each other physically in vivo and are jointly involved in protein–protein interactions that form intracellular signals that regulate cell size, protein synthesis and neoangiogenesis. The complex roles enacted by the gene products serve to explain the diverse clinical features of tuberous sclerosis, but the specific interactions underlying epileptogenesis remains to be elucidated (131).

**116.8.3.2 Lissencephaly and Subcortical Band Heterotopia.** Lissencephaly occurs as an isolated lissencephaly sequence as well as part of a dysmorphic

syndrome (Miller–Dieker syndrome). At least two genes have been identified within the chromosome 17 locus, *LIS1* encoding for platelet-activating factor acetyl hydrolase (PAFAH1B1) (132), and another gene *YWHAE* that encodes for 14-3-3ε(epsilon), a phosphoserine/threonine-binding protein (133). Mutations involving either of the genes can cause lissencephaly; both appear to influence neuronal migration by participating in a highly conserved evolutionary pathway that regulates cytoplasmic dynein function (134).

An X linked form of lissencephaly is recognized in hemizygous males (carrying the abnormal X chromosome), while heterozygous females manifest with a different, distinct neuronal migration defect termed subcortical band heterotopia (SBH) or double cortex syndrome. Here, bands of gray matter isointense with cortical ribbon are distributed within the white matter, separated by a thin layer of white matter representing an entire layer of neurons arrested in their course of migration. Boys with X linked lissencephaly resemble patients with classic lissencephaly phenotype, whereas females with SBH have milder mental retardation, fewer behavioral problems and milder epilepsy. SBH and X-linked lissencephaly are caused by mutation of the doublecortin (*DCX*) gene, with complete absence of the gene product in hemizygous males, while the milder SBH phenotype in heterozygous females results from X-inactivation

**TABLE 116-9 Epilepsy Associated with Malformations of Cortical Development**

Epilepsy Type	Type of Seizure	Clinical and EEG Characteristics	Chromosomal Locus and Mode of Inheritance
Tuberous sclerosis (TSC1) MIM 191100	Infantile spasms	Seizures Mental retardation Hydrocephalus secondary to cerebral glial nodules Hamartomas	Autosomal dominant 9q34

X linked infantile spasms syndrome	Infantile spasms	Mental retardation Epilepsy Absence of cortical dysplasia	Missense/ insertion mutations in ARX
Bilateral Periventricular Nodular heterotopia (BPNH) MIM *300049	Heterogeneous types of epilepsy GTCS, TLE SGTC	Variable age No specific cognitive or neurological markers Heterotopias on imaging	Genetic heterogeneity X linked dominant Xq28 AR forms

Gene testing and molecular diagnostic tests, and laboratories performing such testing is accessible through the NCBI website. <http://www.ncbi.nlm.nih.gov/sites/GeneTests/lab?db=GeneTests>

(lyonization) (135). The *DCX* gene encodes a protein widely expressed in the developing brain (136), which likely plays a critical role in signal transduction in the developing cortex, involving the non-receptor tyrosine kinase cascade (137).

An unusual phenotype of X linked lissencephaly with ambiguous genitalia has also been described caused by a mutation in a highly conserved homeobox gene *ARX* (138). Mutations in the *ARX* gene have now been linked to a wide list of conditions characterized by abnormalities in cerebral development, neurological dysfunction (epilepsy, spasticity and dystonia), autism and mental retardation. Truncating mutations in the *ARX* gene lead to X linked forms of lissencephaly, while missense/insertion mutations lead to other epilepsy phenotypes without cortical dysplasia (139).

Several subtypes of lissencephaly are recognized based on the MRI imaging patterns of the severity and distribution of the agyric–pachygyric cortex (anterior–posterior gradients), the presence or absence of a double cortex, agenesis of the corpus callosum, and other associated malformations of the posterior fossa. The genotype–phenotype relationships and the molecular genetics of lissencephaly and SBH are discussed in greater depth in this paper (140). Furthermore, there is evidence that copy number variations seen with intragenic deletions and duplications also account for a number of cases of lissencephaly and SBH where no abnormalities were identified by mutation analysis (141).

**116.8.3.3 Periventricular Heterotopia.** Isolated periventricular heterotopia (PH) consists of well-differentiated cortical neurons and glia forming nodules in the subependymal zone along the ventricular surface. Individuals with PH are at high risk for epilepsy, although they may have no other neurological signs or external stigmata (142). Seizures starting in infancy have also been reported (143). Both X-linked dominant, as well recessive patterns of inheritance are known. In the majority of patients affected with the X linked form, mutations in the *FLNA* gene on Xq28 are described. The gene encodes a protein filamin A, considered essential for neuronal migration (144). The recessively inherited form is caused by mutations in the gene *ARFGEF2* (ADP-ribosylation factor guanine nucleotide-exchange factor-2) mapping to chromosome 20. The gene product is implicated in membrane and vesicle trafficking within the Golgi network (145,146).

## 116.8.4 Epilepsy Associated with Chromosomal Aberrations

The incidence of epilepsy associated with chromosomal imbalances is difficult to estimate together, and depends on individual conditions (147). Of 400 chromosomal imbalances that were systematically searched, eight disorders with a strong association with epilepsy were identified. These include; terminal deletions of 1q and

1p, Angelman syndrome, inversion duplication of chromosome 15, Wolf–Hirschhorn (4p-) syndrome, Miller–Dieker syndrome, and ring chromosome 14 and 20 (148). In addition to these, specific electroclinical associations have been noted in the epilepsy literature in the Fragile X syndrome, trisomy 12, and Rett syndrome. Trisomy 12p is associated with seizures of the generalized tonic clonic seizures (GTC) or myoclonic types. EEG findings in Trisomy 12p consisted of generalized 3Hz spike wave discharges. Mutations affecting genes (K channels and *GABARAPL1*) localized to 12p region, may lead to increased seizure susceptibility (149). Children with fragile X are reported to have a characteristic EEG pattern with centrottemporal spikes similar to those seen in benign rolandic epilepsy (150–152).

The conditions shown in Table 116-10 merit special attention due to the nature of seizures in the clinical phenotype, electroclinical correlates, and implications for epileptogenesis. In these situations the seizure phenotype is not simply related to gene dosage, but likely influenced by the combined effect on genes in and outside the affected region, as well as environmental influences.

**116.8.4.1 Angelman Syndrome.** More than 90% of children with Angelman syndrome (AS) develop seizures, usually by the third year of life. The seizures display age-dependent features; with febrile seizures or infantile spasms in infancy, evolving into mixed seizures in later life including atypical absences, myoclonic, astatic, and atonic seizures (153). Myoclonic status epilepticus is especially common (154). Seizures in AS often remit after puberty, providing additional support for their age-dependent nature. Highly characteristic EEG patterns are reported (154a,b,155).

A *UBE3A* mutation, uniparental disomy or an imprinting methylation abnormality are sufficient to produce the AS phenotype, but seizures and EEG abnormalities seem to be more severe if the 15q11–13 region is deleted (153b). Genotype–phenotype correlation studies suggest that AS patients with deletions have the highest incidence of seizures followed by those with a mutation in the *UBE3A* ligase gene (156). A study of GABA receptor subunit expression in the cortex of four subjects with AS in a postmortem study has provided useful insights. The key findings suggest; significantly decreased ratios of  $\beta(3)/\beta(2)$  and  $\alpha(5)/\alpha(1)$  subunit protein expression in AS cortex when compared with controls, further using *Xenopus* oocytes to incorporate membrane fractions from AS cortical cells, voltage clamp techniques were applied and receptor pharmacology was found to be altered. These alterations were found to be associated with an impaired extrasynaptic GABA mediated inhibition, but unchanged synaptic GABA mediated inhibition, and a predictable response of epileptic seizures to benzodiazepines (157).

**116.8.4.2 Inversion Duplication of Chromosome 15 (Inv Dup 15 syndrome).** Supernumerary marker chromosomes are small, extra pieces of a chromosomal material attached anywhere along a chromosome. Inversion

**TABLE 116-10 Selected Autosomal Chromosomal Aberrations Associated with Epilepsy**

Epilepsy Type	Type of Seizure	Clinical and EEG Characteristics	Chromosomal Locus and Mode of Inheritance
Angelman syndrome #MIM 105830	GTCS NCSE	Characteristic electroclinical features described (see text)	Deletion Imprinting Uniparental disomy 15q11–q12
Inverted duplication 15 MIM not assigned	Atypical absences Tonic Atonic Tonic-clonic	Characteristic facies, moderate to severe mental retardation, autistic features, hyperactivity EEG Diffuse and multifocal abnormalities, slow spike/polyspike wave abnormalities	Interstitial Dup 15q Inv dup (15)(pter-q12~13;q12~13-pter 4p- deletion *4p16.3
Wolff-Hirschhorn syndrome #MIM 194190	Myoclonic generalized or unilateral Atypical absences	Multiple anomalies "Greek Helmet" facies Characteristic electroclinical features described (see text)	4p- deletion *4p16.3
Pitt Hopkins syndrome	Mixed seizures	Typical Facial dysmorphic features, Hyperventilation episodic Intractable epilepsy	Mutation in Transcription factor (TCF4)
Ring chromosome 20 epilepsy syndrome MIM not assigned	Nonconvulsive status	Characteristic electroclinical features described	Locus of fusion p13q13, p13q13.3 p13q13.33
Trisomy 12p MIM not assigned	GTCS Myoclonic	Characteristic facies Mental retardation, hypotonia, cerebral malformations 3Hz Spike-wave complexes on EEG	Trisomy due to a breakpoint distal to 12p12
Rett syndrome MIM#312750	Partial complex seizures	Acquired microcephaly Autistic features Epilepsy "hand wringing" stereotypes	Xq28 Mutations in the <i>MECP2</i> gene
Fragile X *MIM 309550	GTCS SPS	Characteristic electroclinical features described that resemble the Rolandic trait	Triplet expansion Xq28
Down syndrome #MIM 190685	Infantile spasms	Phenotypic features often permits clinical diagnosis	Trisomy 21 21q22.3

duplication of chromosome 15 (inv dup 15 results in tetrasomy 15p and partial tetrasomy 15q), is associated with severe developmental delay, hyperactivity, aggressiveness, and intractable seizures (158). The predilection for seizures in the inv dup 15 syndrome could also be related to altered GABA receptor function, as three genes coding for GABAA receptor subunits are located on this chromosome (158a).

**116.8.4.3 Wolf–Hirschhorn Syndrome.** The Wolf–Hirschhorn (4p-) syndrome (WHS) is a contiguous gene syndrome. Seizures are reported in 50–100% of cases, with onset usually in the first year. There is a stereotyped electrographic and clinical picture, characterized by mixed seizures (GTC, atypical absences and myoclonic seizures) with characteristic EEG changes described (159). A second critical region WHSCR2 characterized recently, includes a Leucine zipper/EF hand containing transmembrane protein (*LETM1*) gene, that encodes for proteins belonging to the EF hand family of calcium signaling proteins, has been suggested as the gene responsible for the epilepsy phenotype (160).

**116.8.4.4 Rett Syndrome.** The classical form of Rett syndrome is a pervasive developmental disorder affecting primarily girls, with a defined genetic cause (161). The majority of patients with Rett syndrome will experience

epileptic seizures at a median age of 4 years and more than 50% experience a period of active epilepsy of >5 years duration. Distinctive features in the EEG consist of loss of normal background rhythms, frontal central rhythmic theta, and the presence of focal, and multifocal epileptiform patterns (162). Rett syndrome is caused by mutations affecting the *MECP2* gene located at Xq28 (163). The *MECP2* gene appears to be a housekeeping gene working as a transcriptional repressor. The gene appears to have an important role in synaptogenesis and dendritic arborization, in keeping with the pathological findings of reduced numbers of synapses due to either reduced formation or excess formation and pruning (164). Patients with Rett syndrome often have symptoms relating to autonomic dysregulation resulting in a number of behavioral spells often mistaken to be epileptic seizures, in other situations epilepsy may be under diagnosed as true epileptic seizures are overlooked owing to subtle signs and symptoms. Seizures are expressed in an age-dependent manner, and tend to be worse in patients with significant development delay and restricted mobility, and mutation type (p.R294X, p.R255X mutations and C terminal mutations are associated with lower seizure frequency; early truncating mutations are associated with a severe phenotype) (165).

**116.8.4.5 Pitt–Hopkins Syndrome.** This condition carries a typical facial gestalt, and is associated with bouts of hyperventilation, movement stereotypies, severe intellectual disability and intractable epilepsy. Some of the features usually prompt clinicians to investigate these patients for Angelman and Rett syndromes. The facial features are fairly characteristic; deep set eyes, strabismus, thin eyebrows in their midline portion, a large nose, high nasal bridge and flared nostril, protruding philtrum; M-shaped cupid’s bow; fleshy lips and wide mouth with shallow and broad palate; and widely spaced teeth. The helices of the ears are abnormal, dysplastic and thick, the jaw becomes protuberant in later stages. A pathogenic mutation in a gene coding for transcription factor (TCF4) is now shown to be associated with this phenotype (166). The gene encodes a protein that belongs to the “E” protein family that is a downstream target for WNT/ $\beta$ -catenin/TCF pathway. Epilepsy is reported more often in association with missense mutations on genotype–phenotype correlation studies (167).

**116.8.4.6 Ring Chromosome 20 Associated Epilepsy.** There is characteristic electroclinical phenotype associated with a ring chromosome 20 (r20). Though seizures are variable in onset from infancy to adolescence, they become intractable and treatment resistant. Characteristic nocturnal events that may be associated with hallucinations, motor tonic seizures and episodes of nonconvulsive status associated with a fugue-like state and regression are documented. EEG findings are typical during these spells, consisting of long runs of bifrontally dominant slow waves with or without spikes superimposed (168). As dysmorphic features are quite mild in this condition, specific testing for this chromosomal abnormality is indicated in all cases of intractable epilepsy with episodes of confusion, and the characteristic EEG findings.

**116.8.4.7 Down Syndrome.** Seizures occur in 5–10% of persons with DS, in particular infantile spasms (169). The high frequency of seizures in DS was previously attributed to a combination of inherent structural anomalies (brain dysgenesis) and common medical complications of the syndrome (hypoxia ischemia caused by cardiac defects, immune dysfunction with frequent infections, etc.) (169a). Recently, it has been suggested that the association may be more specific (170), with the recognition of the *TNEP1* (C21LR) gene belonging to the superfamily of genes coding for proteins with EPTP repeats, a novel candidate gene as it is localized near the DS critical region (54a).

## 116.8.5 Epilepsy Associated with Inborn Errors of Metabolism

Epilepsy associated with inborn errors of metabolism are characterized by the following clinical features: (1) frequent presentation in the neonatal period, infancy or early childhood years, (2) persistent neurological and

functional impairment in all developmental domains, coinciding or associated with the occurrence of frequent clinical and/or subclinical seizures, (3) resistance to conventional antiepileptic therapy, and (4) adverse effects on cognition, and long-term developmental outcomes. The most striking associations occur in the critical pathways of energy metabolism, neurotransmitter biosynthesis and breakdown. Substrate deficiency (glucose transporter defect, serine and creatine deficiency), as well as accumulation of toxic intermediates (Sulfite oxidase deficiency, nonketotic hyperglycinemia (NKH)) are also involved. Several conditions such as pyridoxine dependency (antiquitin deficiency), pyridoxal phosphate responsive, and folinic acid responsive seizures, creatine deficiency are potentially treatable. Selected conditions are presented in Table 116-11. Success at diagnosis involves evaluation in consultation with an expert in biochemical genetics, and appropriate investigations of blood, urine and cerebrospinal fluid (171). It is important to understand that as a few of these conditions are amenable to treatment, and an early diagnosis can be lifesaving.

Disorders such as, GABA transaminase and succinic semialdehyde dehydrogenase deficiencies involve defects in GABA metabolism. Reduced GABA levels in the brain cause a hyperexcitable state favoring an epileptic predisposition. Pyridoxine-dependent seizures, as well as aromatic acid decarboxylase deficiency, respond to either pyridoxine or pyridoxal phosphate. Pyridoxine functions as a cofactor in the function of the enzyme glutamic acid decarboxylase (involved in GABA synthesis) thus increased cerebral GABA mediated inhibition may be facilitated. Biotinidase deficiency (BTD) is a rare autosomal recessive disorder (172). The seizures in BTD are usually GTC, and less frequently infantile spasms or myoclonic seizures. The EEG shows a burst suppression pattern or multifocal paroxysmal abnormalities. Seizures respond well to administration of biotin. In NKH, there is accumulation of glycine in blood, brain and CSF due to defects in the cleavage system for glycine (173). Glycine functions as an inhibitory neurotransmitter in the brain, and triggers intractable myoclonic seizures and apnea in the neonate (174).

Sulfite oxidase and molybdenum cofactor deficiency are disorders affecting the xanthine metabolism. The presentation is often with very severe and intractable seizures in the neonatal period, often mistaken for a presentation akin to perinatal hypoxic ischemic encephalopathy. Uric acid levels are low in molybdenum cofactor deficiency, and elevated urinary sulfocysteine can be detected in both molybdenum cofactor deficiency and isolated sulfite oxidase deficiency. Imaging studies often demonstrate extensive cerebral atrophy and multicystic white matter change (175).

Cerebral serine deficiency occurs in 3-phosphoglycerate dehydrogenase deficiencies, and a low level of serine in the CSF is considered a marker. Seizures appear to respond to serine supplementation (176). CSF hypoglycorrhachia (low CSF/plasma glucose ratios) is a feature of

**TABLE 116-11 Inborn Errors of Metabolism and Epilepsy**

Inborn Error of Metabolism	Seizure Types	Clinical Features	Mode of Inheritance	Biochemical Abnormalities
Pyridoxine responsive seizures %266100	Multiple seizure types Intrauterine seizures	Prenatal and neonatal onset seizures refractory to treatment with conventional AEDs Responsive to pharmacological doses of Pyridoxine	AR 5q31.2	No specific markers Putative disorder of GABA metabolism
Folinic acid responsive seizures	Seizures tend to be generalized	Intractable seizures in the first week of life Refractory to conventional AEDs Seizures respond to small dose of Folinic Acid	AR	CSF analysis (HPLC) for neurotransmitter metabolites shows an abnormal peak of a hitherto unidentified compound
Succinic semialdehyde dehydrogenase deficiency +271980	Generalized tonic clonic Atypical absence, myoclonic	Psychomotor retardation Hypotonia, Ataxia seizures in 50%	AR 6p22	Increased 4 hydroxybutyric acid in urine, plasma and CSF (Organic acid analysis)
GABA transaminase deficiency +137150	Clonic tonic	Seizures begin in the neonatal period, psychomotor retardation Hypotonia	AR 16p	Rare disorder, increased free GABA levels in the plasma and CSF as well as elevated $\beta$ alanine levels
Non-ketotic hyperglycinemia #605899	Myoclonic encephalopathy	Intractable seizures in the neonatal period Hypotonia Apnea	AR 16q 9p 3p 2p	Plasma and CSF glycine levels are elevated Glycine cleavage system enzymes can be assayed in the liver
3-Phosphoglycerate Dehydrogenase deficiency #601815	Mixed	Microcephaly Psychomotor retardation Intractable seizures Seizures respond to serine supplementation	AR 1q	Cranial MRI shows marked attenuation of signals in the white matter Low serine, and glycine levels in the CSF, Plasma
Pyridoxine resistant Pyridoxal phosphate sensitive seizures	Mixed	Neonatal epileptic encephalopathy Suppression burst pattern on EEG Seizures respond to Pyridoxal phosphate	AR	CSF analysis reduced HVA, 5HIAA Increased 3 methoxytyrosine, threonine and glycine Increased urinary vanilactic acid
Glucose transporter (GLUT1) deficiency #606777	Mixed	Intractable seizures in early life Acquired microcephaly Psychomotor retardation Oscillatory eye movements Treatment response to ketogenic diet, Thioctic acid	AR 1p35	Persistent CSF hypoglycorrachia

GLUT1, which is accompanied by an intractable epilepsy phenotype. The condition responds to the administration of a ketogenic diet (56b). Deficiency of three enzymes; arginine glycine amidino transferase (AGAT), guanidino acetate methyltransferase (GAMT) and creatine transporter result in a clinical syndrome of mental retardation and epilepsy, with creatine deficiency as a common denominator. Measurement of guanidinoacetate in body fluids and demonstration of brain creatine deficiency using in vivo proton magnetic resonance spectroscopy are helpful in establishing a diagnosis. GAMT and AGAT deficiency can be treated by oral creatine supplementation (177). It is of interest that an X linked phenotype of epilepsy and mental retardation has been associated with a mutation in the gene encoding for a creatine transporter gene (SLC6A8) and mapped to the Xq28 locus (178).

#### 116.8.5.1 Mitochondrial DNA Depletion Syndromes.

Another group of disorders involving mitochondrial targeted nuclear DNA genes are the mitochondrial DNA depletion syndromes, which have come to be associated with early-onset epileptic encephalopathies. Germ line mutations in the genes involved in mitochondrial DNA duplication (particularly  $\gamma$  polymerase POLG) and recessive mutations in the nuclear genes (*TWINKLE* and *ANT1*) have been associated with the Alpers as well as other intractable epilepsy phenotypes (179). Children with intractable epilepsy should be screened for POLG mutations, as these individuals would be at risk of developing progressive hepatic failure (180). Valproate should particularly be avoided in scenarios where mitochondrial DNA depletion syndromes are being suspected.

A detailed discussion of this group of epilepsy syndromes is beyond the scope of the present review. Readers are referred to a review article written by the principal author addressing the causes, the clinical presentation, the approach to diagnosis and treatment of epileptic encephalopathies associated with inborn errors of metabolism (181).

## 116.9 CLINICAL AND LABORATORY EVALUATION

The clinical history should focus on elucidating information on the age of onset, seizure type, triggers or precipitating factors, prior history of CNS insult, and existence of comorbid neurological problems (mental retardation, developmental delay, risk factors of stroke, tumor, trauma, CNS infection). In the evaluation of the epilepsy phenotype, the assistance of a pediatric neurologist/epileptologist is essential. Seizure semiology and the electroencephalogram are critical in helping narrow an electroclinical syndrome. The age of onset of seizures, seizure type at onset, evolution and change in semiology must be documented. For instance, onset with prolonged febrile seizures that are hemiconvulsive in the first year of life, followed by the development of myoclonic jerks and other seizure types with cognitive decline would be very suggestive of severe myoclonic epilepsy of infancy. Thus, collecting clinical data, the nature of the epilepsy, progression, presence of associative features are all essential steps in identifying an epilepsy phenotype. In the family history, information on all affected individuals should be collected along the same lines as for the proband. The ethnic background could alert physicians to a founder effect (“Baltic myoclonus” in Finnish population), certain pathogenic mutations and phenotypes may have been described in certain ethnic groups. A family history of consanguinity will suggest autosomal recessive inheritance. Although a matrilineal inheritance pattern points toward mitochondrial cytopathies, these disorders can also show autosomal recessive or dominant inheritance patterns. Other valuable features include a positive family history for seizures/any history of developmental delay/developmental regression/other associated symptoms such as organomegaly/vision and hearing involvement.

The physical examination of the affected individual is directed toward assessing cognitive and developmental abilities, and the presence or absence of focal neurological deficits, and lateralizing signs (preferably conducted by a neurologist in consultation). Most of the patients with idiopathic/cryptogenic epilepsies show little or minimal cognitive or developmental dysfunction, no lateralizing signs, or focal neurological deficits on examination; however if the etiology is symptomatic, then the examination will provide clues to etiology. Anthropometry with special reference to head circumference can provide clues to certain genetic/metabolic syndromes (e.g. macrocephaly in Fragile X syndrome and microcephaly in Rett

syndrome, AS and other inborn errors of metabolism). A careful search for dysmorphic features is warranted, as they may suggest association with specific chromosomal rearrangements.

Examination of the eyes may disclose specific abnormalities of the fundus (cherry red spots, macular changes and pigmentary retinopathy storage disorders, degenerative diseases, and intrauterine infection), cataracts (metabolic disorders). A careful evaluation of the skin for hypopigmented macules (tuberous sclerosis), hyperpigmentation (café-au-lait spots, whorl-like pigmentation), and the presence of port wine nevi on the face may suggest neurocutaneous syndromes (NF1, incontinentia pigmenti, Sturge–Weber syndrome). The presence of visceromegaly, abnormal odors in sweat and urine are additional pointers toward metabolic disease. Examination of genitalia in the case of X-linked infantile spasms would be important to identify the presence or absence of ambiguous genitalia. The neurological examination may help in localizing the structural abnormality to a particular hemisphere or region. Clinical findings such as spasticity, dystonia, and ataxia suggest involvement of specific pathways (pyramidal and extrapyramidal tracts), and regions (subcortical white matter, basal ganglia, cerebellum and connections) within the nervous system.

The neurological history and examination must be supplemented by EEG data to characterize the seizure type and electroclinical epilepsy syndrome. The investigative work up should be individualized for each patient. The seizure types can be classified by the age of onset, type, and with/without fever, frequency, time of occurrence, and association with sleep. In the idiopathic generalized epilepsies, an imaging study is not usually considered as necessary. Video EEG studies may be considered to characterize the seizures and provide electroclinical correlation. The need for other investigations such as imaging arises in the case of a focal- or localization-related epilepsy to rule out a structural lesion or when a symptomatic etiology is suspected. If it is deemed that the clinical profile is not consistent with the well-established clinical phenotypes of genetic generalized epilepsies, other investigations may be selected on a case-by-case basis. Specialized genetic testing may become necessary when the clinical context and imaging studies suggest specific structural abnormalities for which a genetic basis is established (periventricular nodular heterotopia, lissencephaly, and so on). Genetic testing may also become necessary in cases of co-occurrence of epilepsy and syncope, and epilepsy and SUDEP (sudden death in epilepsy) as these conditions have been linked to channelopathies, particularly mutations affecting the potassium channel subunit (KCNQ1) (182).

### 116.9.1 Genetic Investigations and Gene Testing

The role of genetic testing takes on new urgency with the availability now to access such testing on a commercial

scale direct to consumers. Clearly high throughput technologies such as arrayCGH and exome sequencing are set to overtake traditional karyotyping and first generation technologies. The initial work up for every child referred for genetic evaluation should include arrayCGH to detect deletions/duplications, targeted mutation analysis by sequence analysis or detecting methylation status of the *FMR1* gene if indicated. Specific testing for Fragile X, Rett syndrome, Pitt–Hopkins, AS, and ring chromosome 20 become important in the panel of tests to be considered based on the clinical neurological phenotype. In the context of a specific genetic epilepsy syndrome, the age of presentation, the presence or absence of consanguinity, the seizure semiology, and the EEG findings are critically important in making a syndromic diagnosis. For an early epileptic encephalopathy, the targeted mutation analysis could include some of the following genes depending on the abovementioned factors in history and examination (*ARX*, *STXBP1*, *CDKL5*, *SLC25A22*). Similarly, if the phenotype directs the clinician to myoclonic epilepsy or a related “borderland” syndrome, mutation testing for sodium channel mutations would be relevant. In such cases there is a high clinical utility, as a positive test for a mutation could be useful in counseling and in directing treatment choices.

Direct to consumer testing poses many problems while advocates favor the autonomy it brings to patients, critics argue and worry about quality standards, issues pertaining to interpretation of results and the lack of follow-up genetic counseling in the commercial setting. For the geneticist, the ILAE commission on genetic testing has brought out a detailed special report looking at the clinical contexts of genetic testing (diagnostic, predictive, prenatal and carrier), the molecular methods (sequencing, mutation scanning, FISH, targeted mutation analysis, arrayCGH, SNP arrays, and MPLA), and evaluating potential benefits and harms. The special report specifically looks at the clinical validity and utility of diagnostic testing in individuals affected with epilepsy, and in unaffected relatives, as well as the ethical, social and legal implications of such testing. At present, the key message is that despite the availability of gene testing technologies, and many genes being identified, few have current clinical utility in the context of the common genetic epilepsies. The report summarizes the current status of such testing and it is likely that with time and advances in the field, recommendations may change. The reader is referred to this timely and detailed and useful document as the topic merits a separate discussion.<sup>(183)</sup> Links are also provided to web sites of the CDC that give information on the evaluation of genomic testing. <http://www.cdc.gov/genomics/gtesting/ACCE/>. In the data summarized in Tables 116-5–116-7, we have also included information on the availability, accuracy and utility value of available gene tests for the genetic generalized and partial epilepsy syndrome constellations. Gene tests for disorders leading to the progressive myoclonic

epilepsies, epilepsy associated with structural brain malformations, metabolic disorders leading to epilepsy are likely to be discussed in details elsewhere in the textbook.

### 116.9.2 Cranial Imaging

In order to define structural pathology within the nervous system, a cranial MRI should be performed using appropriate coils and protocols to provide high resolution imaging, when evaluating malformations of cortical development and disorders of neuronal migration. Patterns of imaging abnormalities provide critical diagnostic clues for static encephalopathies, degenerative and storage disorders. The use of other techniques such as magnetic resonance spectroscopy can be helpful for measurement of specific metabolites, e.g. a lactate peak (mitochondrial disorders), and the absence of creatine (creatine transporter deficiency).

### 116.9.3 Metabolic Investigations

A consultation with genetics and metabolic specialist is recommended. Ammonia level should be obtained in all encephalopathic individuals or with seizures to rule out urea cycle disorders. Abnormal patterns of plasma amino acids (quantitative) may suggest specific conditions for instance; high alanine levels (mitochondrial disorders), high phenylalanine (untreated PKU should be rare after introduction of newborn screening), low cystine in (isolated sulfite oxidase deficiency), low serine in plasma and CSF (serine deficiency). Urine organic acids should be assayed to rule out any organic acidemias. Low serum uric acid is seen in molybdenum cofactor deficiency, another cause of severe intractable seizures in childhood. Urine dipsticks will be positive for elevated sulfites in sulfite oxidase deficiency. Assays for specific lysosomal enzymes depend on the index of suspicion and clinical profile. DNA-based analysis is used often for mitochondrial point mutations such as in the MELAS, and MERRF syndromes.

*Analysis of cerebrospinal fluid* may provide useful diagnostic markers; elevated CSF lactate (mitochondrial disorders), an elevated CSF/plasma glycine ratio of more than 0.8 (NKH), low serine (serine deficiency) and persistently low CSF glucose to serum glucose ratios (GLUT1 deficiency).

### 116.9.4 Skin, Nerve and Muscle Biopsies

Electron microscopic examination of a skin/nerve biopsy for inclusions is of benefit in the evaluation of lysosomal storage disorders, neuronal ceroid lipofuscinoses, and Lafora body disease <sup>(184)</sup>. Skin should be stored for fibroblast studies, if needed. A muscle biopsy although invasive is the gold standard for diagnosing some mitochondrial disorders. Histopathology and electron microscopy are useful in defining integrity of mitochondrial

structure. Use of special stains such as succinate dehydrogenase and Gomori Trichrome stains can detect red ragged fibers, and cytochrome oxidase negative fibers. All these can suggest mitochondrial pathology; respiratory chain analysis on fresh muscle will also help with diagnosis of respiratory chain defects. An algorithm for the work up of genetic metabolic etiologies presenting with epileptic encephalopathies is suggested (181).

### 116.10 GENETIC COUNSELING ISSUES IN EPILEPSY

Genetic counseling has become a central component of the comprehensive care of the family with a child who has epilepsy. By providing the family with accurate genetic risks for specific epilepsy syndromes, and empirical risks for complex polygenic epilepsies, the physician enables the family to make informed life decisions. The central issues relating to genetic counseling involve the heritability of epilepsy syndrome, the risk of epilepsy in family members and offspring, and the value of genetic tests in epilepsy (10).

The seizure type, supplemented by the history, physical examination and EEG and relevant laboratory investigations will determine recognition of a specific electroclinical epilepsy syndrome, or a clinical phenotype associated with a known single gene defect. The next step in the process is the family history, where a detailed pedigree should be drawn to address key questions (Box 116-1).

The information obtained in combination with clinical data will suggest possible modes of inheritance. For disorders with classical Mendelian inheritance patterns, counseling is straightforward. For instance, in EPM1, and autosomal recessive disorder, with a penetrance of 100%, the sibling risk is 25% (one in four). In benign familial neonatal convulsions, an autosomal dominant inheritance pattern with incomplete penetrance (85%) translates into a 40–45% sibling risk. Matrilineal inheritance patterns suggest a mitochondrial disorder is likely. Counseling for mitochondrial disorders is complex and should take into account heteroplasmy. For disorders with single gene defects, the degree of penetrance and mode of inheritance determine risk.

For the non-Mendelian disorders (i.e. most common idiopathic epilepsies), estimates of risks are best expressed in terms of absolute risk (%) with a range of values as well as to provide comparison figures for the general population. The class of relative (in relationship to the probands) should be taken into account. Sibling and offspring risk estimates are based on the information from epidemiological studies. Risk estimates are influenced by a number of factors including seizure and syndrome type, type of EEG abnormality, age of onset, parental attributes (sex and affected status), and the number of individuals with epilepsy in the family. The risk of developing any form of idiopathic epilepsy by the age 20 years in a sib of an affected proband is around 3%, as

#### BOX 116-1 Key Issues in Genetic Counseling

- Is epilepsy inherited?
- Status of family members
  - Is the proband a twin born, monozygotic or dizygotic
  - Is the cotwin affected or unaffected
  - Number of sibs, affected or unaffected
  - Are parents affected? Mother or Father?
  - Does the proband have any children
  - Affected relatives, class of relatives
- Age of onset of epilepsy in affected individuals
- Seizure type and epilepsy syndrome in affected individuals
- Seizure etiology
- Role of genetic testing in epilepsy

compared to the general population risk of 1%. The risk estimates increase for instance with earlier age of onset, associated EEG patterns, and if one or both parents are additionally affected. Higher risks are associated with specific epilepsy syndrome type. In general, a 6% risk to offspring is considered as a reasonable estimate with an affected mother with idiopathic generalized epilepsy. Though risks in offspring do not seem to be influenced by the seizure type (generalized versus partial), they may be higher for certain specific epilepsy syndromes such as childhood absence epilepsy, and JME. Earlier onset of epilepsy appears to increase risk to offspring, but is not dependent on etiology of epilepsy (Idiopathic/cryptogenic versus symptomatic) Table 116-12 (10,185).

The role of genetic testing in the routine management of common idiopathic epilepsies is limited. The complex modes of inheritance and various confounders that can influence the reliability of a test result preclude routine use of genetic testing in this group. Affected families may opt to undergo genetic testing through participation in numerous research studies and programs such as the gene discovery project of the Epilepsy Foundation of America. For monogenic disorders where genes and common mutations are known and identified, direct mutation analysis is possible in disorders such as the progressive myoclonic epilepsies (EPM1, EPM2, MERRF, and the ceroid lipofuscinoses). These are serious disorders with considerable morbidity and mortality and genetic testing can be justified. Current information on the molecular diagnostic testing, details regarding the specific types of tests and a list of laboratories performing the tests are available through the NCBI web site, <http://www.ncbi.nlm.nih.gov/sites/GeneTests/lab?db=GeneTests>.

### 116.11 PHARMACOGENOMICS ISSUES IN EPILEPSY

The accelerated pace of identification of gene mutations, has opened up opportunities to understand the interactions of gene products, other proteins and drugs within the cell. We have entered into an era of understanding

**TABLE 116-12 Empirical Estimates of Risks of Epilepsy in First-Degree Relatives, and in Offspring**

Genetic Counseling Issues	Proband Attributes	Cumulative Risk Estimate in Terms of Percentage of Siblings by Age 20 Years (%)
<b>Sibling Risk to Age 20</b>		
	General population risk	1
Acute symptomatic	Febrile seizure	2.3
	Febrile seizure then epilepsy	6
Epilepsy age of onset	IGE Onset < age 15	4
	IGE Onset > age 25	2.6
	Overall	2
Epilepsy etiology	Postnatally acquired	1
	Epilepsy and MR/CP	3
Epilepsy seizure type	Partial epilepsy	2.5
EEG pattern	Epilepsy and GSW	6
	Epilepsy + (GSW + PPR) or GSW + multifocal spikes	8
Proband with epilepsy	Parent also affected	8
	Parent also affected either with GSW	12
	GSW in probands and sib	15
<b>Offspring risk for Epilepsy to age 20 where the proband is an adult<sup>a</sup></b>		
Proband attribute	Mother with epilepsy	6
	Father with epilepsy	2.4
Parent seizure type	IGE	3.3
	Pure absence epilepsy	9
	Partial epilepsy	4.6
Parent age of onset	Onset < 20 years	6
	Onset > 20 years	2.8
Parent seizure etiology	Idiopathic/cryptogenic	4.2
	Remote symptomatic etiology	
<b>Specific Epilepsy syndrome related risk to sibs and offspring<sup>b</sup></b>		
Risk type	Syndrome	Estimated Risk %
Sibling risk	Childhood absence	5–10
	Juvenile absence	5
	Juvenile myoclonic	5–7
	Myoclonic astatic	19–20
	Grand mal on awakening	No data
Offspring risk	Childhood absence	7
	Juvenile absence	5
	Juvenile myoclonic	7
	Myoclonic astatic	4
	Grand mal on awakening	5–7

<sup>a</sup>Data summarized from Reference (185).<sup>b</sup>The risks quoted in this section are slightly higher than in first section, the risk to sibling and offspring are similar.

of interaction between drugs and genotype. Variations in genotype will provide a rational basis for the understanding the differences in drug pharmacokinetics, as well as the effect of external factors that influence such differences (age, sex, race, etc.) (186). Proteomics and pharmacogenomics will help us better understand the mechanisms of effectiveness of antiepileptic drugs as well as drug resistance. It has been established for instance that genetic polymorphisms in the ATP-cassette binding member 1 (ABCB1) are associated with a drug resistant epilepsy phenotype (187). Thus, strategies that will block ABCB1, or drugs that will evade or be resistant to the effects of ABCB1, can be designed to improve effectiveness of AED therapy.

Aberrant effects of drugs can also be prevented through knowledge of specific interaction between drug and epilepsy phenotype; for example the use of carbamazepine in the treatment of patients with idiopathic generalized epilepsy presenting with absence seizures (precipitates nonconvulsive status or will induce appearance of other seizure types) (188). The mechanisms underlying this are not well understood but may be linked to the effects of gene mutations on thalamo-cortical networks. Similarly, the use of vigabatrin in the treatment of patients with AS and epilepsy leads to exacerbation of seizures (189). This clinical interaction is also likely linked to the genotype in patients with AS and the effect of vigabatrin in raising cerebral GABA

levels and altered inhibitory extrasynaptic effects on GABA-receptor subunits.

Another example of a pharmacogenomic interaction is the precipitation of hepatotoxicity in patients with mutations in *POLG*, an enzyme involved in mitochondrial DNA maintenance. Mutations in the gene coding for the mitochondrial  $\gamma$ -polymerase can be tested for, and used predictively to determine risk for valproic acid induced hepatotoxicity (180). In the case of *GLUT1* transporter deficiency, the selection of the ketogenic diet as treatment based on the understanding of biochemical aspects of the disorder has been rewarding (56b). An improved understanding of pharmacogenomic interactions in epilepsy will enable the physician in making correct choices of antiepileptic drugs in treatment of seizures, improvements in drug design, the prediction and avoidance of aberrant drug effects, and better strategies in dealing with drug resistance.

## 116.12 EPILEPSY AND PREGNANCY

Pregnancy in women with epilepsy increases the risk of fetal malformations. The risk of teratogenicity was highlighted several decades ago. Prospective studies were only carried out in the early 90s leading to the development of guidelines for care of pregnant women with epilepsy. Fetal malformations were thought to occur at 2–3 times higher rate (around 8–9%) in pregnant women with epilepsy in comparison to the general population (190). There is considerable variability in the reported incidence of birth defects in different studies, but a teratogenic effect attributable to the use of AED is noted, influenced in particular by the type of drug, number of drugs, and dosage during pregnancy (191).

Families with a higher incidence of birth defects, tend to report a higher incidence of malformations in pregnancies exposed to the teratogenic effects of AEDs. This suggests that a genetic susceptibility to malformations may be an added factor influencing the outcome in these pregnancies. Among the front line antiepileptic drugs, valproic acid appears to be the most teratogenic, with a well established dose-related effect, while drug combinations such as phenobarbital+ethosuximide, and primidone+valproic acid were associated with the highest rate of malformations in prospective studies conducted in Europe, and joint Japanese, Canadian, Italian studies respectively (191). Valproic acid exposure during pregnancy has been shown to be associated with a poorer cognitive outcome in children in comparison to carbamazepine, lamotrigine and even phenytoin (192).

Carbamazepine is also associated with the specific risk of spina bifida but to a lower extent than valproic acid (193). The formation of several International Collaborative Registries such as EURAP (European Registry of Antiepileptic Drugs and Pregnancy) as well as other national registries will provide meaningful data on the risks associated with individual antiepileptic drugs.

Women diagnosed with epilepsy and taking AEDs approaching childbearing years should be counseled regarding the risk of teratogenicity. A multidisciplinary consultation involving the geneticist, epileptologist, psychiatrist (if the indication for AED treatment also involves a comorbid psychiatric disorder) and a specialist in maternal-fetal medicine is advised in order to adjust and monitor treatment. A single AED in the lowest dose necessary to effectively control seizures should be chosen several months prior to conception. Valproic acid and polytherapy should be avoided in the first trimester. This will ensure that seizure control will be maintained during pregnancy. Periconceptional folic acid (4 mg/day) is advisable in mothers taking carbamazepine/valproic acid to reduce the risk of neural tube defects. Screening for neural tube defects, ultrasonography and fetal MRI can be helpful in the early detection of congenital anomalies. Additional supplementation of vitamin K (10 mg/day) is advised for 1 month prior to delivery to reduce the risk of hemorrhagic disease of the newborn (194).

### 116.12.1 Fetal Anticonvulsant Syndrome

The most common malformations associated with the use of AEDs include minor anomalies (mid facial hypoplasia, hypoplasia of nail and distal phalanges, and umbilical or inguinal herniae) and major defects (facial clefts, structural heart and neural tube defects, and urinary tract defects) (195). Delayed effects such as developmental delay and cognitive dysfunction are also known to be associated. The periconceptional use of folic acid as supplement, even in small doses as multivitamin supplements may help reduce the occurrence of these defects (196). The major fetal anomalies associated with common AEDs are summarized (Table 116-13).

### 116.12.2 Neural Tube Defects, and Use of AEDs

A 10–20-fold increase in the prevalence rates for spina bifida is noted following exposure to valproic acid in human fetuses. The mechanism by which this teratogenic effect is induced is not fully understood. One potential pathway involves folate metabolism, as folic acid has a known protective effect against neural tube defects in pregnancy, and valproic acid has a known inhibitory effect on folate metabolism.

A number of candidate genes affecting folate metabolism are known, and have been studied including folate receptor alpha (*FR $\alpha$* ), reduced folate carrier, 5,10-methylenetetrahydrofolate reductase (*MTHFR*), to name a few. *MTHFR* is involved in the regulation of intracellular concentration of homocysteine, and elevated homocysteine levels during pregnancy are associated with an increased risk of neural tube defects. This relationship has drawn particular attention as periconceptional administration of folic acid has been shown

**TABLE 116-13 Fetal Anticonvulsant Syndrome-Specific Drug-Related Effects**

Fetal Anticonvulsant Syndrome	Systemic Malformations
Phenytoin effects	Growth retardation Learning difficulties Frontal bossing, ocular hypertelorism, Nail and digital hypoplasia
Phenobarbital	Facial clefts Cardiac anomalies Neural tube defects Hypospadias Hernia Polydactyly
Valproic acid	High forehead Ridged metopic suture Medial deficiency of eyebrows Low set ears, posteriorly rotated Epicanthal folds Flat nasal bridge Thin vermilion border to upper lip Neural tube defects
Carbamazepine	Short nose Long philtrum Hypertelorism Nail hypoplasia Neural tube defects
Lamotrigine	No increase in risk reported in prospective studies

to reduce the risk of neural tube defects (197). Several studies have examined the relationship of MTHFR genotypes and risk of NTDs, as well as the interaction in women who use antiepileptic drugs during pregnancy. Homozygosity for the common 677C→T mutation appears to be associated with an increased risk of NTD in selected populations (198). No definite conclusions can be drawn regarding the interaction between this genotype and in utero exposure to specific AEDs, due to weaknesses in methodology (199).

Interference in methylation of developmentally regulated genes, involvement of genes regulating cell cycle and growth factors are potential mechanistic pathways. Critical perturbations in neurulation involving pathways that are folate sensitive provide an explanation of the influence of antifolate drugs such as valproic acid (200). Although it is now recognized that NTDs are also associated with the use of carbamazepine in pregnancy (201), insights into mechanisms underlying this interaction remain unexplored. Among the newer AEDs, the risk of major congenital malformations appears to be the same as for the general population with the use of lamotrigine as monotherapy (202), but is increased when evaluated for the combination regimen of lamotrigine+valproic acid, an effect similar to that observed with valproic acid monotherapy.

The AED Pregnancy Registry based at the Genetics and Teratology unit at the Massachusetts General Hospital

is a voluntary initiative to collect and analyze information of fetal risk following exposure in pregnancy (<http://www.aedpregnancyregistry.org/about.htm>).

## 116.14 SUMMARY

We have highlighted the diversity of causes, genetic mechanisms and the role of epilepsy genes influencing inherited susceptibility to epilepsy in humans (Figure 116-1). Our understanding of the function of these genes and the proteins that they code (203) for is in its infancy, but even these glimpses underscore the many pathways to epileptogenesis. From ion- and ligand-gated channels, signaling and regulatory molecules, chromosomal aberrations, and defects in intermediary metabolism, the heterogeneity of inherited epilepsy is truly breathtaking. New technologies hold the promise of opening many windows of understanding, and hopefully will lead to methods of early detection, counseling and designing effective therapies for affected individuals and their family dealing with this complex disorder.

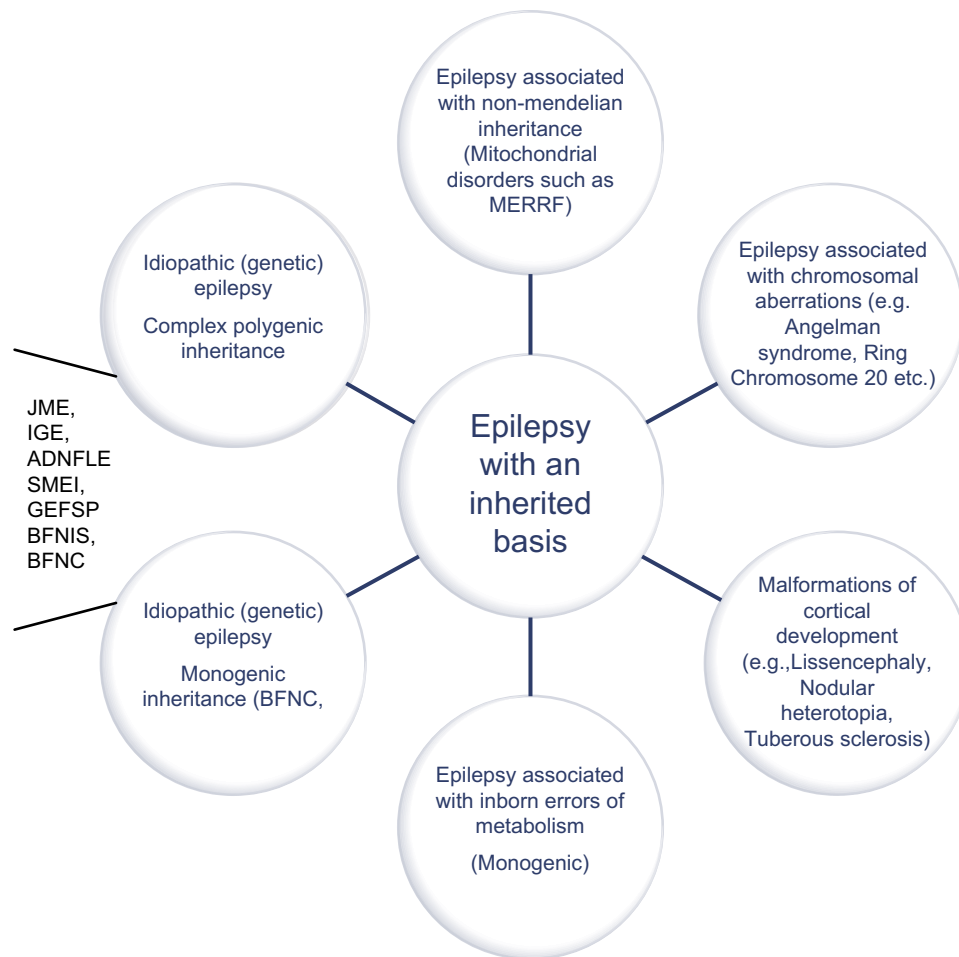

## ACKNOWLEDGMENTS

Asuri N Prasad is indebted to his mentors Carl Stafstrom MD, PhD, and Raman Sankar MD, PhD, for many discussions about this topic in previous collaborations. The authors thank Juanita Carriere, and Janice Little resource associate at the Children's Hospital of Western Ontario for their help with facilitating and accessing reference publications used in the preparation of this manuscript.

## Biographies

**Asuri Narayan Prasad, MBBS, MD, FRCPC, FRCPE** is an tenured associate professor in Pediatrics and Clinical Neurosciences at the Schulich School of Medicine and Dentistry at the Western University, London, Ontario, Canada. He is currently an academic pediatric neurologist on staff at Children's Hospital, and Director of the Pediatric Epilepsy Monitoring Service, London Health Sciences Center. He is also appointed as an associate scientist at Child Health Research Institute (CHRI) affiliated with the Children's Hospital. His research interests focus on pediatric epilepsy, the interface between genetics, metabolism and neurological disorders in childhood. In collaboration with Dr Chitra Prasad, a Neurogenetics and Neurometabolic (multidisciplinary) clinic service has been developed at the Children's Hospital since 2005. He has more than 100 peer-reviewed publications and abstracts to his credit in high impact journals including; "Epilepsia," "Brain," "Neurology," "Journal of Child Neurology," "Molecular Genetics and Metabolism," and the "Canadian Journal of Neurological Sciences." After serving as Secretary–Treasurer, he is currently Vice-President of the Canadian Association of Child Neurology and is a member of the Board of Directors of the Canadian Neurosciences Federation. He is committed to improving the lives of children with epilepsy and neurological disorders and their families.

**Dr Chitra Prasad MD, FRCPC, FCCMG** is an associate professor in the Department of Paediatrics, Section of Genetics and Metabolism, and Director of Metabolic Clinic at the Western University, London, Ontario since 2003. She is a certified pediatrician (Paediatrics from PGIMER (Post Graduate Institute of Medical Education and Research in India), Fellow of Royal College of Paediatrics Canada (FRCPC) and through American Boards in Paediatrics). She received postdoctoral training in medical genetics and inborn errors of metabolism at Children's Hospital, Harvard Medical School, and Boston. She has subspecialized in clinical genetics with certifications in both clinical genetics and biochemical genetics (American College of Medical Genetics and the Canadian College of Medical Genetics). Before coming to London, Dr Prasad held faculty positions in Medical Genetics at the Memorial University of Newfoundland, St. Johns, Newfoundland and University of Manitoba, Winnipeg. Dr Prasad has published many articles on a variety of genetic syndromes and their pathogenesis and metabolic disorders. Her clinical interests include dysmorphology, the pathogenesis of clinical genetic syndromes and inborn errors of metabolism. The main focus for her research has been establishing genotype–phenotype associations in genetic disorders and delineation of new syndromes as well as therapeutic aspects of metabolic syndromes.

# Basal Ganglia Disorders

*Andrew B West, Michelle Gray, and David G Standaert*

Department of Neurology, Center for Neurodegeneration and Experimental Therapeutics,  
University of Alabama at Birmingham, AL, USA

This article is a revision of the previous edition article by Michael R Hayden, Mahmoud A Pouladi and Berry Kremer, volume 3, pp 2703–2736, © 2007, Elsevier Ltd.

## 117.1 INTRODUCTION

The diagnosis and classification of basal ganglia disorders have traditionally rested on the clinical recognition of involuntary movement syndromes. The term “basal ganglia disorders” infers dysfunction of subcortical brain structures that include the neostriatum (caudate nucleus and putamen), globus pallidus (external and internal parts), subthalamic nucleus, and substantia nigra. These anatomic structures constitute the “extrapyramidal motor system,” a concept introduced by Kinnier Wilson in 1912 in his description of familial hepatolenticular degeneration, now called Wilson disease (1).

Clinically, extrapyramidal disorders can be divided into hypokinetic (associated with a paucity of movement) and hyperkinetic (associated with excessive movement) syndromes. The former for the most part is represented by forms of parkinsonism and is characterized by varying components of hypokinesia, bradykinesia, and rigidity, while the latter include dystonia, athetosis, chorea, tremor, and tics (see Glossary). In general, dystonia, chorea, and tremor constitute a phenomenologic continuum that ranges from sustained abnormal postures and very slow writhing gestures (dystonia) to more or less graceful continuous movements (chorea) to rapid and regular oscillating tremor (tremor). Tics are the most complex of hyperkinetic movements, often indistinguishable from voluntary movements only by their frequency and inappropriate timing.

Although the motor aspects are the signature feature of these disorders, and the one which usually brings them to clinical attention, almost all patients with extrapyramidal diseases manifest cognitive or behavioral abnormalities, although sometimes of a subtle nature, that reflect the important role of the basal ganglia in cognitive function (2). In addition, the disease processes that affect the basal ganglia may also involve structures outside these nuclei, leading to more prominent cognitive features that may include psychosis or dementia.

Extrapyramidal structural pathology is a well-established feature of many of the common basal ganglia disorders, including Parkinson, Huntington, and Wilson disease. In other disorders of this class, however, the structural nature has proved elusive: to date, there are no definitive structural changes associated with primary torsion dystonia or Tourette syndrome. The extrapyramidal nature of these diseases has been inferred from the similarities of the movement disorder to other disorders, the effects of pharmacologic treatment, and, recently, the identification of metabolic and neurochemical alterations by modern imaging methods such as positron emission tomography, single-photon emission computed tomography, magnetic resonance spectroscopy, and functional magnetic resonance imaging. The lack of reported pathology is perhaps best viewed as a weakness of the current methods for identifying such pathology.

Recently, the molecular basis of many of these diseases has been established, and the biologic consequences and pathways that are perturbed are now being investigated. This increasing knowledge has already allowed a more rational classification, as well as improved diagnostic accuracy. It is hoped and to be expected that improved and novel treatment modalities for these devastating diseases will follow.

## 117.2 DISEASES WITH PARKINSONISM

The term parkinsonism is used to describe syndromes characterized by hypokinesia, bradykinesia, rigidity, and sometimes tremor. Parkinsonism can be seen in a variety of settings, which include degenerative, metabolic, drug-induced, and vascular disorders. Parkinson disease (PD), a neurodegenerative condition, is by far the most common cause of parkinsonism in most clinical populations. In the case of a patient with parkinsonism, the major diagnostic considerations are PD or the associated conditions: dementia with Lewy bodies, drug-induced parkinsonism, progressive supranuclear palsy, multiple systems

atrophy, Wilson disease, and corticobasal ganglionic degeneration (CBGD). With the exception of Wilson disease (discussed elsewhere), the forms of parkinsonism that are commonly seen are sporadic in nature, lacking a clear pattern of inheritance. There are, however, hereditary forms of PD with classical Mendelian as well as genetic risk factors for PD, and these provide crucial insights into the pertinent mechanisms of neurodegeneration and neurotransmission.

### 117.3 PARKINSON DISEASE

In 1817, James Parkinson described a disease characterized by bradykinesia, hypokinesia, rigidity, and a resting tremor (3). PD is now recognized as the most common neurodegenerative movement disorder and a disease primarily of older people. Onset before age 40 is rare, but after this age incidence and prevalence rise steadily. Prevalence rates in white populations have been estimated to range between 100 and 350 per 100,000 in the general population, but over 600 in populations over age 75 (4). A 1991-European collaborative study yielded an overall prevalence in those over age 65 of 1600 per 100,000, with rates of 3600 per 100,000 reported in those over 85 years (5). Incidence rates are age-dependent, estimated at 114 per 100,000 in the age group 50–99 years but more than 300 over 80 years (6). There is a strong gender effect, with incidence in males which is nearly twice that of females at all ages (7). PD is more prevalent in whites, in whom the lifetime risk of developing the disease has been estimated at 2.4%. In contrast, in people of African or Asian descent, prevalence and risk rates may be considerably lower (8).

#### 117.3.1 Clinical Features of PD

The most commonly used criteria for the clinical diagnosis of PD are those promulgated by the UK Parkinson Disease Brain Bank (9,10). These require the presence of bradykinesia along with at least one additional feature: muscular rigidity, 4–6 Hz rest tremor, or postural instability. There are also several exclusionary criteria designed to screen for other disorders and positive supportive criteria, which include unilateral onset and response to levodopa therapy. The sensitivity and specificity of these criteria are good but not ideal. From a series of 100 autopsy cases that had received a clinical diagnosis of PD by experienced clinicians, only 76 were diagnosed correctly according to standard neuropathologic criteria (9). At least two of the triad of bradykinesia, rigidity, and tremor were present in 99% of the 76 cases during the course of the disease. In these 76 patients, resting tremor was an initial sign in 72%, while the disease started asymmetrically in 77%. In the course of the disease, 76% displayed tremor, while akinetic rigid disease without tremor was present in 24%. Experts in movement disorders have a higher degree of accuracy: in series of 143 autopsies from patients evaluated at the

National Hospital for Neurology and Neurosurgery in London, the positive predictive value of the clinical diagnosis of IPD was extremely high, at 98.6% (72 out of 73). This suggests that experts in the field may apply methods of pattern recognition that are more sophisticated than simple heuristic criteria (11).

The clinical diagnostic criteria emphasize the early features of the disease, when the diagnosis is most in doubt. Later in the course of the disease, balance problems and frequent falls often become problematic. Progressive dysarthria (loss of volume, monotony, and impaired articulation), dysphagia, and drooling are other common features. Depression is common, as is autonomic failure with orthostatic hypotension, and with longer follow up, many patients eventually develop dementia (12). The nosology of dementia associated with PD has undergone considerable evolution in recent years. As currently defined, dementia that develops in the context of established PD is termed “Parkinson disease with dementia” (PDD), while those patients who develop dementia followed by PD are described as “Dementia with Lewy bodies” (DLB) (13,14). The pathology is similar, and some in the field have argued that these should be viewed as different parts of the same spectrum of disease (15). Recent genetic findings strongly support this position as discussed in this chapter.

An interesting development in recent years has been the recognition that in addition to these late, nonmotor complications of PD, there is also a prodromal syndrome preceding the classic motor features (16). The earliest aspects of this may include hyposmia, as well as constipation (likely a consequence of involvement of the enteric nervous system). Indeed, the long-term Honolulu Heart Study showed that frequency of bowel movements was a strong predictor of the occurrence of PD at a follow up 30 years later (17,18). Another strong predictor of subsequent PD is sleep disturbance, particularly REM sleep behavior disorder. Follow up of men with this condition (it is an almost exclusively male disorder) suggests that as many as 50% will develop PD within 5 years of the identification of the sleep disorder (19,20). Together, these observations suggest that there may be a “premotor” state of PD that is potentially identifiable, and may provide an opportunity for intervention with neuroprotective therapies (21).

The natural course of the disease has dramatically changed since the introduction of levodopa therapy in the early 1960s. Prior to the advent of levodopa therapy, widely divergent clinical courses with deterioration within a few years, or survival for 25 years without losing much independence, were reported (22). With medication, the quality of life of PD patients has markedly improved, but age-specific mortality rates of those with PD or other causes of parkinsonism are still twice or more as high as in controls (23). Much of the late morbidity can be attributed to the nonmotor aspects, such as dementia and autonomic failure, which are often

refractory to dopaminergic medications. The development of hallucinations and cognitive impairment is one of the strongest predictors of death in PD (24).

### 117.3.2 Structural and Functional Neuropathology of PD

The best-known neuropathologic features of PD are neuronal loss in the substantia nigra pars compacta, with accompanying occurrence of local free melanin and glial proliferation. The presence of inclusions, termed Lewy bodies, in the remaining nigral neurons is required for pathological confirmation of the disease. Lewy bodies were first described in 1912 by F. H. Lewy, a neuropathologist from the German city of Breslau (currently Wroclaw, Poland) (25). They are typically round intracytoplasmic inclusions with a dense eosinophilic core and a nonstaining surrounding halo, and are often found together with elongated intraneuritic inclusions (“Lewy neurites”) (26). Lewy bodies can be stained by antibodies against ubiquitin and various neurofilaments.  $\alpha$ -Synuclein staining, a major feature of Lewy body immunohistochemistry, was discovered after  $\alpha$ -synuclein mutations were found to be associated with familial PD (see later). Although the presence of Lewy bodies in remaining dopaminergic neurons in the substantia nigra is the signature feature of PD, Lewy bodies and neurites may be found in various other brain areas. In some patients with dementia, cortical Lewy bodies are so prominent, with or without brainstem inclusions, and with or without clinical signs of parkinsonism, that the term diffuse Lewy body disease has been used. In a large cross-sectional study, Braak and colleagues mapped the distribution of Lewy bodies and neurites in more than 700 postmortem brains. Based on these observations, they proposed a sequential evolution of PD, with the earliest manifestations in the dorsal glossopharyngeal and vagal motor nucleus, the raphe nuclei and caeruleus complex, the midbrain (including the substantia nigra), the temporal mesocortex and allocortex, and finally the neocortex (27,28).

The defining neurochemical feature of PD, originally described by Hornykeiwicz and colleagues, is the depletion of dopamine from the striatum (29). This in turn drives the main motor features of the disease—bradykinesia, hypokinesia, and rigidity—and explains the excellent response to pharmacologic dopamine replacement or agonist treatment. There are also a variety of other neurochemical alterations involving other catecholamines and nonaminergic systems, but the specific relationships between these abnormalities and clinical symptoms are less clearly established. For example, due to the profound degeneration of noradrenergic neurons in the locus coeruleus, a mood disorder may arise that accompanies motor dysfunction (30).

The major issue in understanding the neuropathology of PD has always been to find the cause of the progressive

neurodegeneration. Why do substantia nigra neurons—and other neuronal populations—die? In the early 1980s, evidence in favor of environmental causes of PD seemed particularly strong. It was firmly supported by studies in humans and animals that were exposed, accidentally or intentionally, to methylphenyltetrahydropyridine (MPTP). This substance appeared as an accidental contaminant of illicit heroin analog synthesis and turned out to be a highly selective neurotoxin that primarily damages melanin-containing and dopamine-synthesizing neurons (31). MPTP is broken down by monoamine oxidase B into MPP<sup>+</sup>, which significantly interferes with the function of the mitochondrial respiratory chain and results in death of the dopaminergic neurons (32). The discovery of MPTP-induced parkinsonism has always been a major argument in favor of environmental toxins as causes for dopaminergic degeneration in PD, and has supported the notion of mitochondrial abnormalities as risk factors. But, as the 1980s gave birth to the notion of environmental toxins, the 1990s saw the rise of the genetic understanding of PD.

### 117.3.3 Genetics of Parkinson Disease

PD was long considered to have little or no significant genetic contribution to disease susceptibility. While families that clearly inherited disease from one generation to the next were described by prominent neurologists of the nineteenth and twentieth centuries, the debate centered on whether the familial variations of the disease shared enough overlap as parkinsonian disorders to be considered part of the usual spectrum of PD. Early twin studies were interpreted as providing evidence against the existence of important genetic susceptibilities (33–35), but the small sample sizes of these initial studies, reduced penetrance of the disease, and the inability to detect subclinical PD may have been confounding factors. Subsequently, the studies in the late nineteen-nineties yielded the pivotal discovery of  $\alpha$ -synuclein in PD, which uniquely links together lesions that define PD on a pathological level (i.e. Lewy bodies) with rare genetic variation of large effect. Thus, there is no longer a debate over whether there are important genetic susceptibilities in PD: there are now clear and important genetic factors involved, and these will be expanded upon in this chapter; however, it remains unclear the degree to which genetic (or epigenetic) variation ultimately influences disease susceptibility, how many genetic factors are yet to be discovered, and how genetic discoveries will impact clinical diagnosis and treatment.

### 117.3.4 Twin Studies and Familial PD

Initial twin studies were fairly unambiguous about the lack of a genetic involvement in PD. A more recent twin study in a large cohort from the National Academy of Sciences/National Research Council World War

II Veteran Twin Registry advocated the notion that—at least in those in whom PD starts before the sixth decade—genetic factors may play a role (36). Integration of modern imaging techniques identified preclinical loss of dopaminergic input into the striatum in monozygotic twins, initially classified as unaffected with an affected sibling, that are indicative of subclinical PD, demonstrating that twin studies likely underestimate genetic susceptibilities (37). Other recent studies have more closely examined familial aggregation of PD. The odds for any individual to develop PD are increased two to four times in the presence of a first-degree relative with PD (38–40). These odds further increase with increasing numbers of affected relatives and with younger affected relatives. Odds are higher in Caucasians than in African Americans or Hispanics, and they are twice as high for affected male relatives compared with females (39). In general, familial studies and twin studies have supported a much stronger role for genetic factors in individuals with the onset prior to age 50 (e.g. the early-onset PD), but genetic factors could not easily be ruled out in the late-onset disease.

### 117.3.5 Monogenetic Forms of Parkinsonism and Related Disorders

Most patients with PD do not report a family history of disease, and the number of families with evidence of Mendelian transmission (i.e. monogenic) makes up a small percentage of cases, likely 5% or less. The proportion of monogenic PD can be quite difficult to determine, and clinic and referral bias and ethnicity play variable modifying roles. In the families that are identified where PD segregates in a Mendelian fashion, disease often manifests with atypical clinical and neuropathologic features and often starts significantly earlier than idiopathic typical PD. This is congruent with a larger genetic contribution to the early-onset PD versus late-onset typical PD. Of the familial loci that are described in detail, the only known exception to the ‘early-onset’ rule in monogenic PD is the PARK8 locus, encoding the leucine-rich repeat kinase 2 (LRRK2) gene. Although monogenic PD is usually atypical in clinical presentation (save most LRRK2 families), the major rationale for focusing on monogenic PD is that the specific mutation may perturb more severely a pathway that is important in a sporadic typical PD that is of a later onset. Elucidating the associated pathways would also help identify targets for therapeutics and potentially enhance disease diagnosis.

Loci positively identified through linkage analysis in large PD families are usually designated as PARK loci, and these are distributed throughout the genome. However, some PARK loci are susceptibility genes and not associated with monogenic PD. Currently, there are 18 PARK loci defined, although there are presumably many other loci yet to be discovered in smaller monogenic (particularly recessive) families. Generally, loci are definitively

associated with disease when familial segregation of a specific mutation supports pathogenicity within a reasonable doubt. Other loci remain highly tentative and should be understood with caution until future studies can confirm the association. Of note, it is likely not possible to definitively rule out the existence of a particular locus, so the list of PARK loci will always expand but this does not always correlate with identification of clear genetic susceptibilities of disease. For example, type I errors are common in current GWAS studies and some PARK loci derive from GWAS studies. Both definitely associated and speculative genetic factors are described below:

### 117.3.6 Definitively Associated Autosomal Dominant Loci

Currently, there exist two genes where mutations underlie autosomal dominant PD. These genes are associated with the PARK1/4 and PARK8 loci.

**PARK1/4 ( $\alpha$ -Synuclein):** The first family in which extensive clinical and genetic studies led to the identification of a causative mutated gene was described by Golbe and colleagues (41). In this large family of Italian descent, autosomal dominant PD developed at an early age (average 45.6 years), ran a rapid course, and responded well to levodopa. Neuropathologic examination of affected persons revealed striking cortical Lewy bodies consistent with DLB and neuronal loss in the substantia nigra and the Locus coeruleus. In this family, linkage was found at chromosome 4q21–q23, where subsequently a causative base transition (G209A, leading to an A53T substitution at the protein level) in the  $\alpha$ -synuclein gene was found (42). This same mutation, A53T, causes considerable endophenotypic variation, exemplified by the range of ages of onset of symptoms (18 to 80 years) within the same family. The interpretation is that additional strong modifiers of disease must exist (e.g. stochastic probability, environmental effects, genetic modifiers), but the A53T mutation on its own is of very high penetrance. Only a few other families with this mutation have been identified, five of them of Greek descent (43). The A53T mutation is notable since a threonine residue at position 53 in rodent  $\alpha$ -synuclein is the wild-type sequence. Thus, A53T provides a striking exception to the usual rule in genetics that disease-associated mutations tend to occur in evolutionarily conserved residues. In addition to A53T, a German family with an  $\alpha$ -synuclein C88G/A30P substitution and a Spanish family with a G188A/E46K substitution are known (44,45). The Spanish family displays a DLB phenotype as well.

A second type of mutation that involves the  $\alpha$ -synuclein gene has also been identified and originally attributed to the PARK4 locus in the “Iowa kindred.” Similar to the Contursi kindred, autosomal dominant levodopa-responsive parkinsonism occurs prior to age 50, with memory loss and frontal lobe dysfunction,

in conjunction with extensive neuronal loss and Lewy bodies in both subcortical and cortical regions (46,47). Haplotype errors suggested locus copy number variation, and subsequent quantitative of  $\alpha$ -synuclein by polymerase chain reactions demonstrated triplication of the whole region, in which 17 genes are located (48). The triplication is thought to lead to four functional copies of the  $\alpha$ -synuclein gene in the Iowa kindred, and thus to a pathogenic dosage effect, akin to what has been described for trisomy 21 and early-onset Alzheimer disease. Further support for this notion comes from a Swedish-American family with a triplication (49), as well as from a family with autosomal dominant parkinsonism, without cognitive decline or dementia. In this family, a duplication of the  $\alpha$ -synuclein gene was found (50). Disease severity may be directly correlated to dosage of the  $\alpha$ -synuclein gene, where more copies are associated with more severe and earlier onset forms. Thus, simple overexpression of the wild-type protein leads to early-onset PD with dementia as potentially or more potent than the missense mutations originally identified.

Families with mutations in  $\alpha$ -synuclein are exceedingly rare but screening  $\alpha$ -synuclein for mutations is required in evaluating dominant-transmitting monogenic PD families.  $\alpha$ -Synuclein is a very small protein that is expressed in neuronal presynaptic membranes throughout many neurons of the central nervous system but is also expressed in many tissues outside of the brain. Notable protein interactions include the synphilin (synuclein loving) protein and the 14-3-3 class of proteins, both of which can sequester  $\alpha$ -synuclein and modify toxicity (51,52). The  $\alpha$ -synuclein protein is natively unfolded, lipophilic, and can become phosphorylated by Caesin Kinase II in vivo (53,54).  $\alpha$ -Synuclein is also known to interact with metals such as iron and magnesium, but is not considered a canonical metalloprotein. The highest levels of  $\alpha$ -synuclein in the brain are found in various cortical areas and the basal ganglia, particularly in the dopaminergic neurons of the substantia nigra (55). General consensus suggests that  $\alpha$ -synuclein plays a supportive role of vesicular neurotransmitter release at the presynaptic complex. In disease, the protein forms a major component of Lewy bodies and Lewy neurites in the brains of patients with PD (56).  $\alpha$ -Synuclein is not well conserved with evolution as orthologs are difficult to resolve in invertebrate or lower organisms. Knock-down of  $\alpha$ -Synuclein in rodents is well tolerated with subtle effects on dopaminergic transmission (57). Perhaps most striking is that  $\alpha$ -Synuclein knockout mice are resistant to MPTP intoxication, suggesting an integral role for cell death processes in MPTP susceptible neurons (58). Mice that overexpress  $\alpha$ -Synuclein are not further susceptible to MPTP damage, making this conclusion possibly premature (59).

Despite prominent neuronal localization of  $\alpha$ -synuclein, there is also prominent  $\alpha$ -synuclein aggregation in oligodendroglial and neuronal thread-like

inclusions in multiple systems atrophy (60,61). As a noncanonical secreted protein that is readily detectable in human CSF, it is probable that secreted  $\alpha$ -synuclein accumulates in a pathogenic manner in cells that do not endogenously express the protein.  $\alpha$ -Synuclein is a member of a family of three related synuclein genes. No mutations have been found in  $\beta$ - or  $\gamma$ -synuclein that could be related to PD, or any other neurodegenerative disease. The missense mutations that have been described (i.e. A53T) may enhance the rate of spontaneous self-aggregation that has been observed in the wild-type form of  $\alpha$ -synuclein, while multiplication of the  $\alpha$ -synuclein gene may exert increased aggregation propensity through mass action effects (62). How and why  $\alpha$ -synuclein aggregation leads to Lewy body formation and regional degeneration is currently still unclear and not well modeled in animal systems.

**PARK8 (LRRK2):** Families from Japan, the Basque region in Spain, the United Kingdom, Germany, and Nebraska have been reported with autosomal dominant PD linked to chromosome 12p11.2. Onset was later than other familial PD forms, and response to levodopa was uniformly excellent. In late 2004, missense mutations in the leucine-rich repeat kinase 2 (LRRK2) gene were identified (63,64). Soon after the discovery of LRRK2 mutations as a cause of late-onset familial PD, many additional and independent mutations in families from all over the world were identified, suggesting that PARK8 is indeed not a rare cause of familial PD (65–67). The most prevalent known mutation, G2019S, is responsible for about 5% of all autosomal dominant PD, and initial estimates suggested 1.5% of the so-called sporadic cases in European populations. The G2019S mutation, which probably accounts for the vast majority of LRRK2 linked PD, shows high variation in frequency depending on ethnicity. For example, the G2019S mutation can be found in up to 30% of PD occurring in Ashkenazi Jews and North African Arab Berbers (68,69). Of note, in these populations, mutations are nearly as prevalent in patients that report a family history as those that do not, despite clearly sharing the conserved and ancient disease-linked allele. A combination of incomplete penetrance and the aforementioned difficulties (mentioned in twin studies in PD section) in diagnosis are thought to contribute to this phenomenon. LRRK2 mutations clearly illustrate the problems with classification of familial versus sporadic PD in patient populations, and it is thought that many past studies underestimate the contribution of genetics in PD.

All pathogenic LRRK2 mutations thus far identified are missense mutations that alter conserved residues in functional domains. Unlike  $\alpha$ -synuclein, LRRK2 is part of an evolutionarily conserved protein family that can be traceable back to single-cell organisms. LRRK1 and LRRK2 comprise a subfamily of ROCO (Ras-of complex) proteins but in invertebrates such as drosophila, only one member of this family (dLRRK) is detectable, and

this protein is more closely associated with LRRK1. No mutations or linkage of PD with LRRK1 has been found. Thus, studies of LRRK2 function in lower organisms may be viewed with caution. As a mammalian specific protein, the function of LRRK2 in the brain and in other tissue is not clear. Very high levels of LRRK2 protein are detected in kidney and peripheral blood cells, with only moderate expression in the brain (70). LRRK2 is a protein kinase and the most common mutation G2019S in the kinase domain increases kinase activity in vitro 2–3 fold (71), although a substrate for LRRK2 activity has not been verified. Knockout of LRRK2 in mice is well tolerated with only modest descriptions of effects on neurite outgrowth in cultured neurons ex vivo. Other subtle effects on neurotransmitter and dopamine release have been suggested (72).

LRRK2 is a unique (save LRRK1) protein in the human proteome in that both a kinase and GTPase domain are encoded in the same peptide. GTPases are well-known to modify downstream protein kinases, and it is thought that the two enzymatic domains in LRRK2 serve as an intrinsic modifying pathway where kinase activity (or GTPase activity) represent outputs (73). Indeed, PD-causative mutations such as R1441C localize to the GTPase domain and not the kinase domain. Also similar to  $\alpha$ -synuclein, LRRK2 is expressed in many different neurons throughout the brain. Some of these neurons are susceptible to PD and some are not, making an immediate understanding of neuronal vulnerability in PD not forthcoming. The vast majority of individuals with PD that have the G2019S mutation have typical Lewy body formation consistent with sporadic late-onset PD. Thus, some relationship should exist between LRRK2 and  $\alpha$ -synuclein in late-onset PD, potentially analogous to APP and presenilin's in Alzheimer's disease. However, LRRK2 is not known to process  $\alpha$ -synuclein or directly interact despite extensive experimentation and it is thought that the two proteins function in the same pathway but do not directly interact. It is generally assumed that LRRK2 should lie in a biochemical pathway upstream of  $\alpha$ -synuclein as suggested by experimental crosses of double transgenic animals (74).

### 117.3.7 Definitively Associated Autosomal Recessive Loci

**PARK2:** Autosomal-recessive juvenile Parkinsonism (AR-JP) patients from Japan were described with the onset of motor symptoms in their 20s, such as foot dystonia, leg hyperreflexia, amelioration of signs and symptoms after sleep, and a good sustained response to levodopa, but with early occurrence of drug response fluctuations (75). Disease course is overall comparatively benign, and dementia and cognitive decline rare. On neuropathologic examination, loss of pigmented neurons in the substantia nigra and the locus coeruleus can be found, but, contrary to idiopathic PD, no Lewy

bodies were detectable. The gene for this condition was mapped to 6q25.2–q27, and subsequently homozygous deletions within the parkin gene were identified (76). Although the initial reports suggested deletions as the predominant mutational mechanism, subsequent studies showed a wide variety of mutations in many families (77). Moreover, the clinical phenotype extends well beyond Japanese AR-JP: for example, the age at onset in the fifth decade of life has been well-described. Parkin mutations seem to account for at least one third of all families in Europe with autosomal recessive early-onset (<45 years of age) PD (78). In a genome-wide linkage scan of early-onset PD, the parkin gene is highly associated suggesting genetic variability at this site is the most important contributor to the early-onset disease susceptibility (79). Recent evidence suggests that parkin functions together with PINK1 in mediating mitochondrial dynamics (PARK6, described below).

Many cases positive for early-onset- or late-onset PD have been described with only one detectable heterozygous mutation, such as a large deletion or putative pathogenic missense mutation, and another mutation cannot be detected despite exhaustive search (80). The debate over whether these mutations are coincidental to disease or causative, or some susceptibility in between, has not been fully resolved. There is some evidence to suggest that heterozygous deleterious mutations in parkin lead to increased susceptibility to the development of PD. However, parkin spans one of the most common fragile sites in the genome (FRA6E), and large copy number variations comprising deletions within this region are well described in databases that track chromosomal variants in “control” individuals (dGV, database for genetic variation). Thus, it is clear that two separate inactivating mutations each on separate alleles is linked to and probably the major genetic cause of early-onset PD via a haploinsufficiency model. However, it is not yet clear whether heterozygous mutations lead to increased susceptibility to PD.

Most discovered missense mutations in parkin are very difficult to attribute to disease susceptibility, as many benign alterations are likely to exist. However, functional studies suggest that, for at least the confirmed pathogenic mutations, parkin function is compromised in a number of ways by the presence of associated mutations (81). Parkin encodes an unusual E3 ubiquitin ligase together with an ubiquitin-like domain not usually found on this class of enzyme. The C-terminal sequence of parkin has two RING domains with an in-between RING domain, and RING domains are thought to facilitate transfer ubiquitin to target proteins through both K63 or K48 linkages (82). Parkin mutations have been described in all functional domains, particularly in the RING motifs (78). This links parkin to the ubiquitin-proteasome protein degradation machinery and suggests that parkin mutations impair breakdown of specific proteins. But parkin's E3 ligase-specific substrates have not

yet been established. Immunohistochemistry and in situ hybridization studies showed protein-containing and gene-expressing neurons widely distributed in the substantia nigra, the raphe nuclei, and the basal ganglia, but also in laminar structures such as the cortex and the hippocampus. In patients with parkin mutations who lack Lewy bodies, the protein is completely undetectable; in idiopathic sporadic PD, the protein seems present in normal amounts.

**PARK6 (PINK1):** In a large Sicilian family with recessive disease in four affected individuals, a genome-wide homozygosity screen revealed a locus at the short arm of chromosome 1. Phenotypically, affected patients showed the early-onset (range 32 to 48 years) parkinsonism, with slow progression and sustained response to levodopa (83,84). These clinical features were expanded in additional families from Europe and Asia, broadening the possible age-at-onset range from 18 to 68 years, with or without foot dystonia, with or without sleep benefit.

Valente and colleagues then identified two different homozygous mutations affecting the kinase domain of PINK1 (PTEN-induced kinase 1) in three consanguineous PARK6 families (83). Additional mutations have been described, both affecting the kinase domain and outside this important catalytic site. PINK1 is mitochondrially located and may exert a protective effect on the cell that is abrogated by the mutations, resulting in increased susceptibility to cellular stress. These data provide a direct molecular link between mitochondria and the pathogenesis of PD. Similar to parkin, individuals with a PD phenotype have been identified who are heterozygous for single pathogenic mutation. In these cases, heterozygous loss of PINK1 function may constitute a risk factor for PD, but as with parkin, further studies are required to assess risk and delineate pathogenic versus benign alterations.

PINK1 encodes a serine threonine kinase together with a mitochondrial localization signal (MLS). PINK1 has been demonstrated to provide protection from mitochondrial dysfunction and apoptosis, and removal of PINK1 is suggested to induce defective mitochondrial membrane potential and mitochondrial morphology (85–87). These defects are efficiently rescued by parkin, suggesting PINK1 functions upstream of Parkin in mediating mitochondrial function. Recent data from *Drosophila* and other model systems suggest that PINK1 and parkin act in a selective autophagic pathway to remove depolarized and damaged mitochondria from neurons (88).

**PARK7 (DJ1):** In a genetically isolated population in the Netherlands, Van Duijn and coworkers diagnosed four related patients with the early-onset parkinsonism at or before age 40 and a good response to levodopa (89). Homozygosity mapping identified a locus at 1p26. In an independent set of four consanguineous families, these linkage results were confirmed in at least three families. The phenotype was similar to the Dutch family, with

levodopa-induced dyskinesias occurring after treatment. In the original Dutch family, a homozygous deletion that contained DJ1 only cosegregated with the disease phenotype, while a homozygous L166P substitution in one Italian family confirmed DJ1 mutations as causative of recessive early-onset PD. Deletions and nonsense DJ1 mutations have been described, but these are an exceedingly rare cause of early-onset PD, and postmortem descriptions have not been possible, and it is unknown whether  $\alpha$ -synuclein aggregates are present. A number of missense mutations have also been described that are suggested to destabilize the protein and lead to reduced expression.

DJ-1 is expressed in most tissues throughout mammals and is a very evolutionarily conserved gene with orthologues detectable in single-celled organisms. DJ-1 may function as a redox-sensor protein with antioxidative activity in both neuronal and glial cells. Although knockout of DJ-1 in mice is well tolerated and only subtle defects described (e.g. hypersensitivity to MPTP exposure), DJ-1 removal may result in mitochondrial phenotypes that include reduced membrane potential, increased fragmentation, and accumulation of autophagic markers (90). It has been suggested that DJ-1 may act to maintain mitochondrial function in the context of oxidative stress. Thus, the direct interaction between the parkin/PINK1 pathway and DJ-1 is not clear, but there appears to be overlap in terms of the overall maintenance of mitochondrial dynamics in susceptible neurons.

**PARK9 (ATP13A2):** In a Jordanian consanguineous family, five affected sibs suffered from early-onset parkinsonism, with onset of symptoms between ages 12 and 16 years. Spasticity, supranuclear upgaze paresis, and dementia were additional nonparkinsonian features. Treatment with levodopa resulted in incomplete improvement of parkinsonian features. Magnetic resonance imaging (MRI) of the brain showed globus pallidus atrophy and later generalized brain atrophy (91). The gene was later mapped to 1p36 (92). But although this disorder, called Kufor–Rakeb disease by the original authors, has been assigned a PARK locus number, the condition does not meet criteria for a PD-like disorder. Postmortem descriptions have not been available and it is unknown whether  $\alpha$ -synuclein deposits are present in affected areas.

Mutations were identified in the ATP13A2 gene and the encoded protein has been described as a lysosomal membrane protein with encoded ATPase function that may traffic inorganic cations and other substrates in lysosomes (93). Pathogenic mutations in ATP13A2 are suggested to affect localization and stability of the protein via disruption of the transmembrane domain. Overexpression of ATP13A2 has been described to protect from  $\alpha$ -synuclein in some model systems (94). Although PARK9 may not represent a parkinsonian disorder, the function of APT13A2 in disease may reveal novel aspects of  $\alpha$ -synuclein biology relevant to PD.

*PARK14 (PLA2G6)* and other recessive parkinsonism diseases with complex phenotypes. Mutations in the *PLA2G6* gene were identified in a consanguineous Pakistani family with Neurodegeneration with Brain Iron Accumulation 2B (NBIA2B) (95), and as with *PARK9*, *PARK14*-associated disease does not meet criteria for a PD-like disorder. The clinical and pathological phenotypes associated with NBIA2B can be considered similar to those of *PANK2* mutations in NBIA1 syndrome (Hallervorden–Spatz disease). As with NBIA2, NBIA1 patients can develop a parkinsonism dystonia like phenotype. Neuropathological examinations reveal pronounced Lewy bodies in NBIA1. Mutations in the *NPC1* gene cause Niemann–Pick Type C, and neuropathological examination also reveals Lewy bodies in some cases. These genes and their encoded proteins may provide insight in  $\alpha$ -synuclein function in disease in sporadic PD.

*PARK15 (FBX07)*: Homozygous mutations in the *FBX07* gene were first identified in an Iranian family with a parkinsonian-pyramidal syndrome, and additional mutations identified in *PARK15* linked families of Italian and Dutch descent (96). Although no pathology has been reported in cases with mutations, the phenotype and pallidal syndrome features suggest strong overlap to *Park9* and *Park14* and divergence from typical PD linked phenotypes. F-box proteins like *FBX07* are cofactors for a class of E3 ubiquitin ligases proteins called SCFs that function in phosphorylation-dependent ubiquitination (97).

### 117.3.8 Putative (Unconfirmed) Monogenic loci

*PARK3*: Families with autosomal dominant PD have been described in which a locus at 2p13 (*PARK3*) is involved in the development of parkinsonism that closely resembles sporadic disease, both clinically and neuropathologically (98). Onset age in these families was 59 years, similar to sporadic PD. In two German and Danish *PARK3* families, with an assumed but unproven common founder, the penetrance of the mutation is below 40%. Particular haplotypes at this locus have repeatedly been found to be associated with the onset age in samples of PD patients (99). The *PARK3* locus includes several dozen genes and but no overt gene mutations have been identified despite exhaustive investigations. It is possible that a monogenic cause of PD does not localize to this region but rather a modifier of age of disease onset. A notable candidate is the sepiapterin reductase gene, which encodes a protein critical for dopamine biosynthesis.

*PARK5*: Ubiquitin Carboxyl-Terminal Hydrolase L1 (*UCHL1*). In two patients from one family, a putative mutation in the ubiquitin carboxyterminal hydrolase-L1 gene (*UCHL1*) has been described from a candidate-screening approach (100). This C277G transversion

results in an I93M amino acid substitution in a highly conserved region. No other families with mutations in this gene have been identified, and *UCHL1* linkage to PD should be considered putative.

*PARK10*: A susceptibility locus for late-onset idiopathic PD (not a monogenic PD-associated locus) was assigned as *PARK10* from studies in Icelandic PD patients (101). This locus has not replicated in GWAS studies or populations with strong genetic overlap with Icelandic populations such as Norwegians. In addition, the locus includes hundreds of genes and has not been refined or reconfirmed in the Icelandic population.

*PARK11*: A 39.5cM region on the long arm of chromosome has been described as linked to disease in North American PD families under an autosomal dominant model of inheritance (102). However, linkage to this region has not been observed in other populations. Missense mutations in the *GIGYF2* have been nominated as pathogenic in small PD families. However, other studies have demonstrated that these putative mutations are not pathogenic for PD, and the assignment of *GIGYF2* as a PD-associated gene is currently tentative (103). Other candidate genes for *PARK11* have not been nominated.

*PARK12*: Pankratz et al. employed a sib pair-based genome wide approach and identified a large region of Xq21–q25 associated with PD (genomewide  $p=0.04$ ) (102). As yet, no mutations have been identified in these patients, and the region has not replicated as associated in other studies.

*PARK13 (Omi/Htra2)*: Loss of function mutations in the gene encoding *Omi/Htra2* have been proposed in a candidate gene approach in German PD patients (104), but other studies suggest these rare alterations are not causative for PD but benign variants.

### 117.3.9 Important Genetic Susceptibilities in PD

*MAPT (PARK locus not assigned)*: The microtubule-associated protein Tau (*MAPT*) is primarily expressed in neurons in the brain and is thought to regulate the organization of microtubules in the cytoskeleton architecture. Tau coassembles together with tubulin and is enriched in axons. Tau positive inclusions are the pathological hallmarks of a number of neurodegenerative diseases that include Alzheimer's disease, corticobasal degeneration, PSP, and frontotemporal dementia with parkinsonism linked to chromosome 17. Although tau pathology is not common in PD and those PD cases described with tauopathy may be the result of a coincidental but separate disease, genetic variation in the *MAPT* gene associated with PD is arguably the most reproducible finding in PD genetics. *MAPT* resides in a large block of strong linkage disequilibrium, and the major haplotype named H1 is confirmed as a PD risk factor in every major GWAS

study in PD that involves European subjects (105). Interestingly, tau haplotypes are not associated with susceptibility to AD despite clear tau pathology in disease. Emerging evidence suggests that  $\alpha$ -synuclein may modify and compromise the ability of Tau to regulate cytoskeleton dynamics.

**PARK1/4 ( $\alpha$ -synuclein):** While extremely rare gene copy number alterations and missense mutations lead to early-onset PD with dementia, common genetic variants have been reproducibly demonstrated to modify susceptibility to PD. Some evidence suggests that  $\alpha$ -synuclein alleles that are associated with PD lead to increased transcription and expression (62). It is thought that the enhanced expression is not as high as that caused by a gene duplication, but that the mild elevation predisposes to disease in a dose-dependent manner. A complex repeat polymorphism located 10kbp upstream of the translation start site in the  $\alpha$ -synuclein promoter named REP1 is associated with PD, in addition to SNPs in the 3' end of the gene. Other SNPs within the  $\alpha$ -synuclein gene captured in GWAS studies reproducibly highlight  $\alpha$ -synuclein as a consistently associated gene that modifies PD susceptibility.

**PARK8 (LRRK2):** While missense mutations can potentially cause PD in European populations, these mutations are extremely rare in the Far-East Asian populations. However, in these Asian populations, several common nonsynonymous variants G2385R and R1628P potentially modify PD susceptibility (106,107). These variants are not common in European populations. A recent meta-analysis of the G2385R variant suggests a striking combined odds ratio for PD of 2.55 (95% CI, 2.1–3.1).

**GBA (PARK locus not assigned):** Recessive mutations in the glucocerebrosidase gene (GBA) lead to Gaucher's disease, which is considered a lysosomal storage disorder. Sidransky and colleagues found that parents and second-degree relatives of Gaucher's disease that presumably carry a heterozygous mutation in GBA often have PD (108). GBA mutations are more common in Jewish populations and occur at much higher frequencies in PD cases (>25%) versus PD-negative controls.

**PARK16/17:** Recent GWAS analyzes have nominated loci on 1q32 (PARK16) and on chromosome 4 (rs11248060, PARK17) (109). The underlying genes and their functions are not yet clear, or the reproducibility of the associations.

**HLA-DRB5 (PARK18):** One GWAS study identified a HLA haplotype associated with sporadic and late-onset disease. The association peak at SNP rs3129882 is a non-coding variant in HLA-DRA and is thought to segregate with modifiers of expression of HLA-DR and HLA-DQ (110). Some evidence suggests that PD-affected brains show an upregulation of DR antigens and DR-positive reactive microglia, linking the immune system on both a genetic and pathologic level to PD.

### 117.3.10 The Future of Genetic Research in PD

The identification of specific genetic causes of PD has revolutionized research in neurodegeneration in many ways. It is fitting that the first gene identified in familial PD,  $\alpha$ -synuclein, is likely the principal modifier and most important protein for disease. Genetic studies coupled with functional approaches have strongly suggested that the main genetic contribution relevant to  $\alpha$ -synuclein and PD centers on the regulation of  $\alpha$ -synuclein on a transcriptional level. The ideas that mutations and genetic variability should underlie proteins that comprise the majority of the pathological aggregate in the disease have been a common theme and confirmed in dozens of disorders. Thus, genetics guides pathology and pathology guides genetics in a feedback loop, with the overall goal of improving diagnosis and treatment.

$\alpha$ -Synuclein genetics and pathology extends beyond PD into many other neurodegenerative disorders that are disparate from PD on both clinical and pathological levels. The discovery of causative mutations in LRRK2 uniquely provides direct insight into pathological mechanisms specific to typical late-onset PD. Studies into LRRK2 shed light onto genetics of PD as a whole. First, dominant mutations of high penetrance were found at rates in many populations that were not predicted by earlier genetic studies and acutely illustrates that GWAS studies are not likely to be powered to detect rare variants of strong effect without tens of thousands (perhaps hundreds of thousands) patients included in the study. Second, LRRK2 studies demonstrate the lack of apparent utility of patient-derived family histories in deciding whether an individual or family has monogenic PD of dominant transmission, since many PD cases of reported sporadic origin harbor pathogenic mutations that are not de novo in origin and yet highly penetrant for disease. Third, the discovery of LRRK2 through genetic studies provides a potent example of how new pathways and targets for therapeutics can be identified for complex disease.

The autosomal-recessive forms of parkinsonism have unquestionably provided insights into biochemical pathways important for the health of neurons in the basal ganglia in neurodegeneration. However, their importance in terms of late-onset typical PD susceptibility has not been clear. Divergent clinical phenotypes and diverse cellular pathways have been implicated, with arguably the most excitement generated by the 'mitochondrialopathies' associated with PINK1, Parkin, and DJ1. Through identification of the biochemical pathways associated with loss of function mutations in these pathways, it is hoped that new therapeutic targets are resolved that can modify neurodegeneration in both early- and late-onset typical disease.

However, while the identification of LRRK2,  $\alpha$ -synuclein, and the plethora of genes associated with

recessive parkinsonism have been instrumental in shaping research objectives, there are limited numbers of families of sufficient size worldwide to detect new monogenic forms of PD. There is a large focus on GWAS studies that are powered to detect common variation of moderate to weak effects. It is likely that in the very near future, studies involving greater than ten thousand patients will identify new genetic susceptibilities. Exome resequencing has not been described in PD to any large extent but will likely help identify rare mutations of large effect in new genes that may help resolve common biochemical pathways in PD. Finally, the integration of gene expression data in affected brain tissue together with coding and noncoding DNA variation (i.e. epigenetic variation) will likely contribute to understanding PD on a genetic level. If the past is the best predictor of the future, we have only scratched the surface of understanding the genetics of PD.

## 117.4 PARKINSON PLUS SYNDROMES

Progressive supranuclear palsy (PSP, or Steele–Richardson–Olszewski disease) (111), multiple system atrophy (MSA) (112), and corticobasal degeneration (113) fall into the category of Parkinson plus syndromes. These are chronic diseases that in some ways may resemble PD. All three were initially considered sporadic diseases, but there is now substantial evidence that genetic factors, particularly related to the *MAPT* tau gene, play an important role in PSP and corticobasal degeneration. MSA, still considered a sporadic disease, may clinically resemble autosomal dominant cerebellar ataxia and therefore may present a diagnostic problem.

### 117.4.1 Progressive Supranuclear Palsy (OMIM 601104)

After PD, PSP may be the most prevalent cause of degenerative parkinsonism, with an estimated prevalence rate ranging between 2.5 and 10.5 per 100,000 (114). The mean annual incidence rate for those over age 50 may be about 5.3 per 100,000 (115). The disease is typically one of aging people, rarely starting before age 40 and rising in incidence over the decades up to 14.7 for those between 80 and 99 years old. It runs a relentlessly progressive course, with median survival of about 5.5 years. Clinically, the core features of the disease are early-gait and balance problems: vertical (also horizontal) saccadic slowing that develops into gaze paralysis, particularly on downward gaze; parkinsonism; axial dystonia; and cognitive decline (“subcortical dementia”) (116,117). A response to levodopa is temporary and slight, at best. Although PSP is generally considered to be a sporadic disease, familial cases consistent with autosomal dominant transmission have been described, not all of them typically in terms of clinical presentation (118).

Neuropathologically, neuronal degeneration and loss is primarily found in the striatum, the globus pallidus, the subthalamic nucleus, and various brainstem areas, among which is the substantia nigra (119). Characteristic fibrillary depositions (straight filaments) that immunostain with antibodies against the tau protein have been found in these structures. Abnormal accumulation of tau protein is also present in astrocytes. Therefore, PSP is considered a “tauopathy,” like frontotemporal dementia or Alzheimer disease. Interestingly, among the tau species deposited in PSP brains, the four-repeat tau (one of its six isoforms) seems enriched (120).

The link with tau is further demonstrated by a repeatedly confirmed association with a specific tau haplotype, often called H1, that seems to confer an increased susceptibility to PSP (121). Tau mutations have never been identified in the familial cases that have been described, apart from rare atypical cases with exon 10 mutations that may be more like frontotemporal dementia. A recent GWAS study involving more than 2000 cases of PSP has demonstrated association with several genes including *STX6*, *EIF2AK3*, and *MOBP*, encoding proteins for vesicle-membrane fusion at the Golgi-endosomal interface, for the endoplasmic reticulum unfolded protein response, and for a myelin structural component. This study also confirmed two independent variants in *MAPT* affecting risk for PSP, one of which influences *MAPT* brain expression (122).

### 117.4.2 Corticobasal Ganglionic Degeneration/Corticobasal Degeneration

The rare disease corticobasal ganglionic degeneration (CBGD) resembles PSP and may be actually confounded with it. The classical diagnostic feature of CBGD is unilateral asymmetrical dystonia or ideomotor apraxia (“the alien limb syndrome”), often associated with cortical sensory abnormalities. Cognitive decline, particularly manifesting as a subcortical dementia, is prominent in this disease. Like PSP, neuronal tau inclusions are a feature of CBGD type 1, including the enrichment of four-repeat tau (123). And like PSP, association with the tau-containing H1 haplotype has been found (124). Indeed, although pathological criteria for CBGD have been established (125), there are patients where the features overlap with those of PSP (126). These close similarities have led some to suggest that the two disorders be merged into a single entity, but in their classical forms, the clinical features are so distinct that most practitioners regard them as separate disorders. Although “familial CBGD” has not been described, this may turn out to represent semantic confounding. Those families with parkinsonism, subcortical decline, and asymmetrical dystonia or limb apraxia will probably be reported as having frontotemporal dementia with parkinsonism.

### 117.4.3 Multiple Systems Atrophy

In our current state of knowledge, this prevalent and highly incapacitating disease must be considered as a true sporadic disease. MSA is almost as prevalent as PSP (115). Survival is somewhat longer, with a median of up to 9 years. Clinical features are a mix of parkinsonism, cerebellar ataxia, autonomic dysfunction (orthostatic hypotension, bladder disturbances, erectile dysfunction), and pyramidal tract dysfunction, particularly of the lower legs (127). Another distinctive feature is the lack of dementia in these patients (128). Neuropathologically, silver-staining fibrillary inclusions (“argentophilic inclusions”) are found in oligodendroglia and neurons in affected brain areas (129). These inclusions are strongly immunoreactive for  $\alpha$ -synuclein, thereby establishing MSA as an “ $\alpha$ -synucleopathy,” similar to PD and diffuse Lewy body disease (130).

### 117.4.4 Wilson Disease

Rarely, Wilson disease may present as a parkinsonian syndrome, particularly in young patients. Although rare, it should be part of the differential diagnosis, as it can be easily diagnosed and is amenable to treatment. This condition is discussed elsewhere.

### 117.4.5 Dystonias

Dystonia is a clinical syndrome, identified by its characteristic features: sustained muscle contractions, twisting, and abnormal postures (131). Dystonia may be the main, or only, clinical symptom, or it may be seen in association with a variety of other disorders, such as stroke, PD, or other degenerative disorders of the brain. When dystonia is the primary symptom and there is no identifiable other disorder that is the cause, it is termed “primary” dystonia, with dystonias related to other diseases classified as “secondary dystonia” (132). Comprehensive lists of possible causes of secondary dystonia Table 117-1 can be found in the literature (133).

Most of the cases of primary dystonia encountered by clinicians are sporadic in nature, and of uncertain etiology. As in PD, however, in recent years genetic etiologies for primary dystonia have been identified, and these have begun to shed some light on the fundamental mechanisms responsible for these disorders.

## 117.5 GENERAL CLINICAL FEATURES OF THE DYSTONIAS

Dystonia is a movement disorder characterized by sustained muscle contractions, frequently causing twisting and repetitive movements or abnormal postures (131,134). Physiologically, it is characterized by concurrent contractions of agonist and antagonist muscles. Apart from dystonia, some additional features of disordered movement

**TABLE 117-1 Possible Causes of Secondary Dystonia**

#### Hereditary Neurodegenerative Diseases

Ataxia telangiectasia
Dystonia with striatal basal ganglia calcifications
Dystonic lipidosis
Glutaric acidemia type I
GM1 gangliosidosis
GM2 gangliosidosis
Hallervorden–Spatz disease
Hartnup disease
HGPRT deficiency
Homocystinuria
Huntington disease
Leigh disease
Metachromatic leukodystrophy
Neuroacanthocytosis CT lucencies
Neuronal ceroid lipofuscinosis
Neuronal intranuclear inclusion disease
Niemann–Pick disease, type A/B
Niemann–Pick disease, type C
Pallidal atrophies (including DRPLA)
Pelizaeus–Merzbacher disease
Spinocerebellar ataxias
Wilson disease

#### Sporadic Degenerative and Nondegenerative Diseases

Basal ganglia infarction,
Drugs (acute intoxications; dyskinesia)
Encephalitis
Head trauma
Intoxications
Multiple sclerosis
Vascular malformations and tumor
Drugs (acute intoxications: dystonia; chronic: tardive dyskinesia)
Perinatal damage
Spinal cord disease
(Manganese, CO, CS <sub>2</sub> )

#### Disorders Simulating Dystonia

Congenital	Muscular; postural; Klippel–Feil syndrome
Neurologic	Posterior fossa tumor; syringomyelia; Arnold–Chiari syndrome
Ocular	IVth nerve palsy
Psychiatric	Atlantoaxial subluxation;
orthopedic	ligamentous cervical problems; bone disease
Others	Hiatus hernia; Sandifer–Kinsbourne syndrome

CT, computed tomography; DRPLA, dentatorubral-pallidoluysian atrophy; HGPRT, hypoxanthine guanine phosphoribosyltransferase.

Adapted from Calne, D. B.; Lang, A. E. Secondary dystonia. *Adv. Neurol.* 1988, 50, 9–33.

are commonly encountered in conjunction with dystonia. There is often dystonic tremor; clinically, this is distinguished from the more common forms, such as essential tremor, by the coarse nature of the movement, the irregular frequency, and the association with fixed dystonia. Characteristically, the so-called sensory tricks (geste antagoniste) are able to correct the abnormal posturing.

For example, the gentle touch of the index finger may correct the twisted position of the head in torticollis.

Dystonic movements can be classified according to their distribution: focal (a single body part affected), segmental (spreading to a contiguous body part), multifocal, hemidystonia (left or right), or generalized. Age of onset is also important. In dystonia, it is customary to distinguish between early- (prior to age 28) and late-onset diseases (135). The rationale for selecting this particular age cutoff is based on the biology of DYT1 dystonia, as discussed below. Childhood-onset cases often start with focal or segmental dystonia that eventually spreads to affect multiple parts of the body. Marsden and Harrison, in a review of 42 patients, found that 80% of the cases with onset before age 11 had progression to severe generalized dystonia (136). Patients with generalized dystonia usually had onset in childhood or adolescence, and almost always by age 40. In contrast, about 70% of those with focal distribution tended to have onset after age 40 (137). In fact, focal or segmental dystonia could even start over age 70. In a series of 560 patients, Fahn and associates found a median age of onset of 8 years for generalized dystonia, with a peak between 6 and 10 years. Segmental dystonia had a median onset of 40 years but a bimodal distribution, with a small curve at a young age and a broader curve later in life. Focal dystonia has its mean onset at age 45 (137). Thus, the earlier the age of onset, the more likely there will be an evolution to generalized disease. These are of course generalizations, and the outcome will depend to a great extent on the underlying etiology.

The most common types of dystonia encountered in a general neurology practice are late-onset focal dystonias, including cervical dystonia (torticollis), oromandibular dystonia and blepharospasm (Meige syndrome), occupational dystonias (e.g. writer's cramp), isolated limb dystonia, and spasmodic dysphonia. Axial dystonia, involving the paraspinal musculature and twisting the body in grossly abnormal postures, is often part of generalized dystonia but is uncommon as an isolated symptom. In patients with late-onset focal or segmental dystonia, the movement disorder rarely generalizes.

### 117.5.1 The Neurobiology of Dystonia

The neurobiological mechanisms of dystonia are one of the most important unsolved questions in basal ganglia disorders (134). One of the key barriers to progress has been the lack of a clear association between the clinical symptoms of dystonia and corresponding pathological changes in the brain (138). It is clear that lesions in the striatum (caudate and putamen), globus pallidus, and thalamus may cause secondary dystonia, but these represent only a small minority of the cases of dystonia. Only a handful of cases of primary dystonia (either focal or generalized)

have been studied pathologically, and these have revealed no clear evidence for neurodegeneration or other structural changes. Clinical imaging methods such as CT and MRI usually do not reveal any abnormalities, although these studies may be helpful in excluding secondary dystonia, particularly in the case of focal or hemidystonia.

Recent work with functional and neurophysiological methods has begun to shed some light on brain abnormalities in dystonia. PET studies of dystonia patients have provided evidence for cerebral functional networks that are dysregulated in dystonia (139,140). Interestingly, some of these networks are shared by dystonias with different genetic etiologies (141). There is also recent evidence for changes in structural connectivity of the brain in dystonia, as revealed by diffusion tensor imaging. Interestingly, changes can be seen in individuals who carry genetic mutations for dystonia but do not manifest the symptoms (nonmanifesting carriers (142,143). From a physiological perspective, alterations in somatosensory processing, both at the level of the cortex and below, have been described consistently (144–147). The previously mentioned effects of “sensory tricks” support the role of sensory dysregulation as a core feature of dystonia (148).

Although the bulk of the evidence points to involvement of the basal ganglia in dystonia, there is also evidence for participation of other neural structures, particularly the cerebellum (142,149). In several animal models of dystonia, the movements have been traced directly to cerebellar abnormalities. Imaging in patients consistently reveals abnormalities in the activity of the cerebellum in dystonia. LeDoux and Brady reported a case series and extensive review of the literature of secondary forms of cervical dystonia (150). They observed that the majority of the cases had lesions in the cerebellum or associated with brainstem afferents to the cerebellum. In contrast, lesions isolated to the basal ganglia were uncommon in this series.

On the whole, the current level of understanding of the neurobiology of dystonia is unsatisfactory. It is clear that many forms involve abnormal function of the basal ganglia, but there is also participation of the premotor and motor regions of the cortex, sensory systems, the thalamus, and the cerebellum. In some cases, peripheral sensory feedback seems to be a contributor. Disentangling the relative roles of these components will require further improvements in methodology for studying the function of the human brain, as well as a clearer understanding of the proximate causes of dystonia.

### 117.5.2 Clinical Genetics: The Various Forms of Primary Dystonia

In the past decade, mapping and cloning efforts have resulted in a consistent classification of primary dystonias. From a clinical genetic perspective, a subdivision into autosomal dominant, recessive, X-linked, and sporadic forms remains a useful first approach to classification and counseling. Accurate assessment of the mode

of inheritance can sometimes be difficult because of the low penetrance of the various disorders in most families. The application of a few simple clinical guidelines can be helpful in making a correct diagnosis and in the selection of informative laboratory investigations.

**117.5.2.1 Autosomal Dominant Idiopathic (or Primary) Early-Onset Torsion Dystonia: DYT1 (OMIM 128100)** This is one of the most common forms of primary torsion dystonia, occurring with increased frequency in people of Ashkenazi Jewish descent. Onset is almost always in childhood or adolescence, with focal limb onset that over the years spreads to the other limbs and the axial musculature. Cranial and laryngeal involvement is rare. The disease is transmitted as an autosomal dominant disorder with incomplete penetrance of about 30% (135,151–153). Linkage data from both non-Jewish and Jewish families established the DYT1 locus to the 9q32–q34 region, although linkage to this locus could be excluded in some early-onset families. A common haplotype of 9q alleles was found among affected Ashkenazim, and it was concluded that the vast majority of early-onset cases in the Ashkenazi Jewish population are due to a single mutation that has been estimated to have occurred approximately 350 years ago. This mutation may have arisen from the northern part of the historic Jewish Pale of settlement (Lithuania and Byelorussia) (154).

The gene for DYT1 was cloned in 1997 by Ozelius and colleagues (151). They identified as the pathogenic mutation a GAG trinucleotide deletion in a conserved region of a novel ATP-binding protein called torsinA. The gene was renamed TOR1A. This deletion results in loss of one of a pair of glutamic acid residues. The mutation was found in all affected and obligate carrier individuals with chromosome 9-linked dystonia, including four non-Jewish families. A second mutation in TOR1A, an 18-bp in-frame deletion near the C-terminal part of the protein (Phe323–Tyr328del), was found in two patients with early-onset dystonia and myoclonic features (155). Whether this last alteration constitutes a pathogenic mutation is unclear: in both patients, a Leu196Arg mutation was also identified in exon 5 of the  $\epsilon$ -sarcoglycan gene. Mutations in this gene are commonly associated with myoclonic dystonia (see discussion of DYT11 later).

The DYT1/TOR1A gene has high homology to three additional vertebrate genes as well as to nematode and *Drosophila* genes (134,153). The TOR1A gene is located next to one of its homologs, TOR1B; both genes belong to the HSP/Clp and AAA+ ATPase superfamily of chaperones. Northern blot analysis of TOR1A revealed two ubiquitously expressed transcripts of 1.8 kb and 2.2 kb and an additional low-abundance transcript of 5 kb that was detected in the fetal brain, lung, and kidney, as well as in the adult brain, heart, and pancreas (151). Widespread expression was found in many brain areas, including the dopaminergic neurons of the substantia nigra (156). The deduced protein, torsinA, is a 332-amino acid, approximately 37-kDa protein that contains an

ATP-binding domain and a putative N-terminal leader sequence, as well as a membrane-spanning region that may be necessary for membrane translocation and targeting. Its function is uncertain, although most evidence suggests that it is endoplasmic reticulum resident protein involved in secretion and trafficking (157). Mouse models constructed either by introducing the human mutation into *dyl1*, the mouse homolog of TOR1A, or by transgenic expression of the human protein has not produced animals with obvious dystonia (158). Many of these animals do, however, have subtle motor phenotypes, and it has been suggested that they may model the “nonmanifesting carrier” state of DYT1 dystonia (159).

The GAG deletion results in the loss of one of a pair of glutamic acid residues in a conserved region near the carboxyl terminus of the protein. Mutational analysis of most of the coding regions and splice junctions of TOR1A and TOR1B failed to reveal additional mutations in typical early-onset cases of patients who lack the GAG deletion, in dystonic individuals with apparent homozygosity in the 9q34 region, or in an individual with late-onset dystonia who did share the common 9q34 haplotype (153).

Mutational analysis has also made possible a better appreciation of the clinical features of DYT1. The most common form is indeed an early-onset (prior to age 20 to 30) limb dystonia that gradually may generalize but typically spares craniocervical muscles. However, cases of isolated focal or segmental dystonia have been described (160–162). In patients with nonfamilial dystonia, particularly in those without generalized dystonia, with late onset, or with cranial dystonia, the number of individuals with a DYT1 mutation is very low. Brassat and colleagues found five sporadic patients with the mutation out of a group of 100 sporadic individuals (163). Four of these five had early-onset generalized dystonia. Among 300 cases with late-onset focal/segmental dystonia, only three tested positive for the GAG deletion (161).

**117.5.2.2 Autosomal Dominant Primary Dystonias: DYT6** In two Mennonite Amish families, dystonia started between 6 and 38 (mean, 18.9) years, with cranial or cervical dystonia in about half of those affected. Most of the later disability was caused by cranial or cervical manifestations. The locus was mapped to 8p21–q22 (DYT6); an identical haplotype in the region linked the two families to a recent common ancestor (164). DYT6 dystonia has recently been found to be caused by mutations in the transcription factor THAP1 (165). This has a large number of potential downstream targets, but interestingly one of the genes regulated by THAP1 appears to be TOR1A (166). Identification of the DYT6 gene has enabled molecular screening, and has revealed that THAP1 mutation may be a cause of apparently sporadic dystonia (167). Despite the interest in this disorder, there are so far no pathological studies of the condition.

**117.5.2.3 Autosomal Dominant Primary Dystonias: Other Forms (DYT7, DYT4, DYT13)** Apart from the DYT1 and DYT6 families that have been identified, many families in the world have been described in whom dystonia segregates as an autosomal dominant trait, not linked to chromosomes 8 or 9. Several different loci have been assigned, and more are expected to exist. Leube and coworkers identified a family with seven persons definitely affected by late-onset (28 to 70 years) focal dystonia (torticollis, dysphonia, writer's cramp) and six possibly affected (hypertrophic neck muscles, postural hand tremor). Linkage to 18p was demonstrated (168). In one Australian family with at least five generations of affected family members, in whom onset ranged from 13 to 37 years, a linkage to 9q could be excluded, and the locus in this family has been designated DYT4 (169). In a large, non-Jewish, three-generation Italian family, autosomal dominant ITD started at an average age of 15 years. Manifestations started in the cervical or craniocervical region or upper limbs and slow progressed to other body regions over decades. The gene was subsequently mapped to 1p36.32–p36.13 and the locus called DYT13 (170). In all of these autosomal dominant families, the same general clinical principle seems to hold true as in the DYT1 families. Early-onset dystonia is often limb onset and tends to generalize; late-onset dystonia often presents as a focal or segmental disorder and tends to remain localized.

**117.5.2.4 Autosomal Dominant Hereditary Progressive Dystonia with Marked Diurnal Fluctuations, or Dopa-Responsive Dystonia: DYT5 (OMIM 128230)** Hereditary progressive dystonia with marked diurnal fluctuations (HPD), or dopa-responsive dystonia, is a rare condition first described in 1976 by Segawa in Japan (171). However, despite its low prevalence, the biochemical and genetic basis for this disorder is currently well known, and it provides clues as to the neurobiology of dystonia in general. Several cases have been described, but many more cases may go unreported or indeed undiagnosed. The true prevalence of this disease, therefore, is unknown, but it seems to be more common in Japan than in North America or Europe.

Initial descriptions of HPD emphasized onset in the first decade, initially with asymmetrical dystonic foot posturing and walking impairment, with progression and gradual involvement of other extremities (172,173). The disease progresses over the first two decades but stabilizes from the third decade onward. Marked diurnal fluctuations are present, with dystonia being partially alleviated in the morning and aggravated during the course of the day. Particularly impressive is the effect of L-dopa, which gives marked and sustained relief in relatively low doses without the long-term side effects that occur in the treatment of

PD. Nygaard and colleagues, calling the disease dopa-responsive dystonia (DRD), later described additional aspects of the phenotype, such as early-developmental and motor delay-resembling cerebral palsy, later-life parkinsonism, late-onset parkinsonism in previously unaffected family members, and lack of fluctuations in 25% of patients.

HPD/DRD is an autosomal dominant disorder with low, sex-related penetrance and a female preponderance that may be as high as 4:1. The HPD/DRD gene was initially mapped to a 20-cM region on chromosome 14q. Using a candidate gene approach, the Japanese group then found that one of the tetrahydrobiopterin-synthesizing enzymes, GTP cyclohydrolase I, mapped to this same 14q region (174). Four variations in four families were identified: three single-base changes that predicted nonconservative amino acid substitutions in highly conserved regions of the GTP cyclohydrolase I gene (GCH1), and a 2-base insertion frameshift mutation. In one family, no mutation was found. In all families, however, GTP cyclohydrolase I activities in phytohemagglutinin-stimulated mononuclear blood cells of affected members was reduced from 2% to 20% of control values. Mutant fusion proteins, expressed in *Escherichia coli*, showed no detectable enzymatic activities for two of the base substitutions. In cases of severe loss of activity of GTP cyclohydrolase 1, presumably under 2% and presumably associated with mutations on both alleles, the affected infant displays mental retardation, epilepsy, disturbances of tone and posture, abnormal movements, hypersalivation, and swallowing difficulties (175).

Many mutations—missense, nonsense, and frameshift mutations—in the coding or noncoding regions or in the exon–intron junctions of GCH1 have been reported in patients with dominant HPD/DRD all over the world; most of these are new mutations (176). In about 40% of cases with a typical phenotype and low GTP cyclohydrolase 1, no mutations can be found. In such cases, mutations in the GCH1 promotor, enhancer, or transcriptional regulatory domains, as well as large genomic deletions, have been implicated (177).

GTP cyclohydrolase I is the rate-limiting enzyme for the biosynthesis of tetrahydrobiopterin, the cofactor for tyrosine hydroxylase, which is the first and rate-limiting enzyme of DNA synthesis. Apparently, mutations in GTP cyclohydrolase I lead to dopamine synthesis impairment that can be bypassed by administration of the dopamine precursor L-dopa. In a large series of 66 cases, the effects of L-dopa therapy were immediate and dramatic, with daily doses as small as 50mg being effective (178). Treatment duration of up to 23 years has been reported, and response fluctuations developed only rarely, leading to speculation that these latter cases might represent juvenile-onset PD rather than DRD. Thus L-dopa is the treatment of choice, as well as a diagnostic tool.

A markedly decreased striatal dopamine concentration and a mild decrease of levels of the dopamine metabolite homovanillic acid could be demonstrated in a postmortem brain (179). Homovanillic acid concentration decrease can also be detected in cerebrospinal fluid. But, contrary to PD, the striatal dopaminergic deficit is not caused by nigrostriatal neuronal loss, as the number of substantia nigra neurons is normal, and a normal pattern of tyrosine hydroxylase immunoreactive fibers is present in the striatum. Furthermore,  $^{18}\text{F}$ -dopa uptake on PET, which provides a measure of the functional integrity of the nigrostriatal dopaminergic projection, is normal (180,181). This integrity could very well explain the prolonged success of low-dose L-dopa therapy.

**117.5.2.5 Myoclonic Dystonia: DYT11 (OMIM 159900) and DYT15 (OMIM 607488)** This relatively mild form of dystonia is increasingly recognized in various parts of the world (182). In most cases, onset is before age 20, with presentation in the face, neck, and arms. Both dystonia and myoclonic jerks, often subtle, occur in patients, with different predominance in different patients, even within one family. In some patients or families, myoclonus, rather than dystonia, may be the most prominent sign. Quite characteristically, alcohol alleviates the movement disorder (183) and alcoholism may develop as a consequence. Clonazepam may be a long-term treatment alternative. Obsessive-compulsive phenomena may segregate with the movement disorder (184). Epilepsy may also be part of the phenotypic spectrum (185).

After the initial finding of linkage to 7q21 was confirmed in phenotypically similar families, mutations in the  $\epsilon$ -sarcoglycan gene (SGCE) were identified in most families (186).  $\epsilon$ -Sarcoglycan is a component of the dystrophin-sarcoglycan complex, and it is widely expressed in both nonneuronal and brain tissues. Although a variety of loss-of-function mutations have been described, all of them seem to result in parental origin-dependent penetrance; that is, the disease is more likely when the gene is inherited from the father than when originating from the mother. Maternal imprinting of SGCE is the most likely explanation, and this has indeed been observed (187). A second locus at 18p11—DYT15—has been identified in a Canadian family with myoclonic dystonia (188). Thus, the phenotype may be genetically heterogeneous.

**117.5.2.6 Autosomal Dominant Rapid-Onset Dystonia with Parkinsonism: DYT12 (OMIM 128235)** Various families with rapid-onset dystonia with parkinsonism have been described that share the following unique features: onset within a few hours to days to weeks, although a more protracted course has been described; severe bulbar manifestations, including dysarthria; and parkinsonism. Onset in these families varied from early to late adulthood. Penetrance

seemed incomplete, but male-to-male transmission has been described (189,190). The finding of linkage to chromosome 19 led to the subsequent identification of six mutations in the Na<sup>+</sup>/K<sup>+</sup>-ATPase  $\alpha$ 3 subunit gene (ATP1A3) in seven unrelated families with this unusual form of dystonia (191). The connection between the genetic disorder in energy metabolism and the abrupt and permanent nature of the symptoms has raised speculation that the defect may predispose the brain to an energy crisis under stress and subsequent neurodegeneration, but there is so far no clear evidence for a structural abnormality in DYT12. In a mouse model system, interactions between the basal ganglia, cerebellum, and thalamus appear important for generation of the phenotype (192).

**117.5.2.7 Recessive Forms of Dystonia: DYT2 (OMIM 224500)** It has always been assumed that cases of recessive primary dystonia could be identified, and the finding of affected offspring from consanguineous marriages has been used to support this possibility. In four Spanish Gypsy families, with three of them consanguineous, recessive inheritance seemed likely (193). Low penetrance of dystonia in families with an autosomal dominant form of the disease may simulate recessive disease, which has made identification of some of these genes difficult.

The best documented examples of recessive dystonias are those due to tyrosine hydroxylase deficiency, that resemble early- (childhood-) onset L-dopa-responsive dystonia (194–196). Much rarer genotypes, which often present with a much more severe phenotype, are 6-pyruvoyl-tetrahydropterin synthase deficiency (197), sepiapterin reductase deficiency (198), and aromatic L-amino acid decarboxylase deficiency (199).

**117.5.2.8 X-Linked Dystonia (“Lubag”): DYT3 (OMIM 314250)** An X-linked form of generalized dystonia with parkinsonism (XPD) has been identified in the Philippines, where this distinct syndrome reaches endemic proportions on the island of Panay (200–202). The disease is locally known by the name of lubag (twisting) and may have its onset between the ages of 12 and 48 years (mean,  $38 \pm 8.0$  years). In an assessment of 42 cases, the initial manifestations have been variably found in the lower or upper extremities, the trunk, or the face, in order of decreasing frequency (200). Major manifestations include gait abnormalities (90% of patients), leg dystonia (79%), oromandibular dystonia (64%), neck dystonia (57%), blepharospasm (57%), and truncal dystonia (52%). Dystonia tends to generalize within 1 to 11 years. Characteristically, 35% of the cases displayed parkinsonian signs: bradykinesia, rigidity, tremor, or loss of postural reflexes. Those with parkinsonism had a significantly later age of onset (40.5 years) than those without (32.4 years). Medications that may be useful in other forms of dystonia, such as trihexyphenidyl or L-dopa, are not effective in lubag.

XDP is genetically homogeneous and has its origins on the Panay Island of the Philippines. The locus for XDP has been mapped to the proximal long arm of the X chromosome at Xq12–q13.1. One gene encoded in this region is TAF1, a transcription factor expressed in the nuclei of neurons in the striatum and other regions of the brain (203), but there are several other candidates within the region, all of which exhibit strong linkage disequilibrium.

## 117.6 MANAGEMENT AND TREATMENT

The symptomatic treatment of ITD is a process of trial and error. It has been recommended to start with increasing doses of l-dopa, as some of these cases may not represent ITD but instead may be l-dopa-responsive dystonia. If this fails, anticholinergic medications (e.g. trihexyphenidyl) constitute the drugs of choice. The dose should be gradually increased until adverse effects (drowsiness, xerostoma, blurred vision, impotence, urinary retention, and obstipation) become limiting. In general, only high doses yield adequate effects, and these doses are best tolerated by young patients. After this, baclofen, carbamazepine, or benzodiazepines may be tried, although their efficacies are less than that of anticholinergics. Local injections of botulinum toxin in dystonic muscle groups is currently the treatment of choice for focal dystonias. This is a safe and very effective treatment but it must be repeated frequently. Both the patient and the clinician should be aware that, in general, treatment effects will be partial at best. A completely new and novel approach to treatment is the application of deep brain stimulation in patients with generalized dystonia. Preliminary results with this approach are encouraging (204,205).

## 117.7 CHOREIC DISORDERS

### 117.7.1 Huntington Disease

**117.7.1.1 Prevalence.** Multiple epidemiological surveys of Huntington disease (HD) have been presented from different parts of the world, including northwest Europe, the United Kingdom, Scandinavia, North America, Australia, Japan, and South Africa. While recorded rates differ, there is general agreement that the frequency of HD in populations of Western European descent is between 3 and 7 affected individuals per 100,000 of the population. However a few areas, such as certain regions of Venezuela or Scotland, show particularly high or low prevalence of HD. The disease is less frequent in Japan, China, Finland and in African blacks.

**117.7.1.2 Natural History.** A very broad definition of “age of onset” is the first time any neurologic or psychiatric symptoms appear that represent a permanent change from the normal state. The age at which signs of symptoms for HD occur has a mean of around 40

years and a standard deviation of approximately 10 years (206). The earliest age of onset has been approximately 2 years (207,208) (juvenile-onset), and patients with onset of the disorder in their 80s and even early 90s have been noted.

HD does not have a specific single presenting sign or symptom. Patients may exhibit early subtle changes in executing motor programs, with minor changes in coordination and involuntary movements. In addition, an insidious and slow deterioration of intellectual functions as well as mild personality change has been reported (209). The duration of HD is about 15 years, with no differences between the sexes (206). Survival with HD has not significantly changed over the past 50 years, which reflects the failure of medical therapy to delay disease progression. Even though the mean duration in many different studies has been constant, there are marked individual variations, extending up to as much as 40 years from time of onset on rare occasions. It would appear that, in some families, HD follows a milder course with longer survival.

#### 117.7.1.3 Clinical Manifestations and Diagnosis.

Most individuals affected by HD will initially display minor motor abnormalities. These include general restlessness, abnormal eye movements or abnormal optokinetic nystagmus, hyperreflexia, impaired finger tapping or rapid alternating hand movements, and excessive and inappropriate movements of the fingers, hands, or toes during emotional stress (209,210), as well as mild dysarthria. Minor motor abnormalities usually precede the obvious signs of extrapyramidal dysfunction by at least 3 years. Gene carriers with a completely normal neurologic examination have a 3% chance of being diagnosed within the next 3 years (209).

A definitive diagnosis of HD can be made when the following features are present: (i) demonstration of the pathognomonic mutation, a trinucleotide CAG repeat expansion is the only mutation observed; (ii) progressive motor disability involving both involuntary and voluntary movement; and (iii) mental disturbances, including cognitive decline, affective disturbances, and/or changes in personality. These features indicate that the disease is already manifested. The diagnosis of HD depends on a clinical examination. In the absence of clinically defined signs and symptoms but the presence of the mutation, the patient is presymptomatic. Demonstration of atrophy of the caudate nucleus and the putamen by CT or MRI provides additional support for the diagnosis. PET may reveal a decrease in the uptake and metabolism of glucose in the caudate nucleus before structural tissue loss becomes evident.

#### 117.7.1.4 Presentation of HD: Early- and Late-Onsets.

**Juvenile Onset.** Approximately 10% of all patients with HD have onset before age 20. In contrast to adult cases, bradykinesia and rigidity are conspicuous early, dominating the neurologic findings in about 50% of juvenile cases (206,211). Chorea is present in almost all cases

but is often of short duration and is superseded by rigidity (206). Frequent falls, dysarthria, clumsiness, hyperreflexia, and oculomotor disturbances are frequent in children with HD and occur early. Although difficult to assess in HD, cerebellar dysfunction is more prominent than in adult patients (210).

Mental deterioration in juvenile HD is first manifest by declining school performance. Over the years, a severe progressive dementia develops. Epileptic seizures, which are no more frequent in adult HD patients than in the general adult population (1%), are more common in early-onset cases with an estimated 30% to 50% of juvenile patients affected (206,211). Partial or generalized, tonic-clonic or absence seizures may all appear. Seizures should be differentiated from myoclonic jerks, which also rarely occur in adult cases. The epilepsy of juvenile HD patients is often difficult to control.

**Late-Onset.** In contrast, the manifestations in late-onset disease are less severe. Approximately 25% of all cases will display first signs and symptoms after age 50, and in these patients, the disease will follow a slower progression than usual (212). Chorea is the presenting motor disorder, and gait disturbances and dysphagia are common, though not severe. Cognitive impairment, although invariably present, may be less debilitating than in younger patients (212). A later onset is associated with a slower disease progression, as measured by functional disability. Even prior to clinical diagnosis, persons carrying the mutation can demonstrate cognitive dysfunction. Specifically, presymptomatic HD carriers have deficits in shifting strategy, psychomotor speed, recognition memory, planning, and verbal fluency (213–215). At this point, the impairments are subtle as many studies were unable to detect any difference in cognitive function prior to motor onset (216,217).

**117.7.1.4.1 Motor Dysfunction. Chorea.** Chorea is the major motor sign of the disease. These involuntary movements are continuously present during waking hours, cannot be voluntarily suppressed by the patient, and worsen during stress. Choreic movements of the face are common and present as pouting of the lips, irregular grimacing, twitching of the cheeks, and alternate lifting of the eyebrows and frowning. The neck is often involved, causing forward or backward bending of the head, or rotation. Breathing may become irregular. In the limbs, there is frequent flexion and extension of the fingers. The legs may be alternately crossed and uncrossed and the toes flexed and extended. Chorea is a feature of HD in over 90% of patients, increasing during the first phase (~10 years) of the patients' illness. With advancing duration, features of bradykinesia, rigidity, and dystonia become more evident. Chorea is seen less frequently in patients with juvenile onset (206,218). These cases often represent the so-called rigid Westphal variant (219,220).

**Bradykinesia and Rigidity.** Bradykinesia and rigidity are infrequent in the early phases of adult-onset HD.

However, they gradually appear until they often dominate the final stages of the illness, in which the patient will become severely rigid and grossly akinetic (210,219). Early in the illness, bradykinesia alone may contribute to an impairment in voluntary motor performance (221). In both juvenile and adult rigid cases, a coarse-resting tremor, distinct from a parkinsonian tremor, may complement the clinical picture (220).

**Dystonia.** Dystonia, characterized by slow abnormal movements and abnormal posturing, is infrequent in the early-symptomatic period but worsens and becomes a prominent feature toward the later stages of the illness (210).

**Oculomotor Dysfunction.** Oculomotor disturbances, apart from being among the earliest signs in the transitional phase, are present in the vast majority of affected patients. Slowing of saccades may be seen in up to 75% of symptomatic individuals, especially in early-onset cases, more particularly affecting vertical rather than horizontal movements (222,223).

**Voluntary Motor Dysfunction.** An early sign is impairment of voluntary motor function (221,224). Patients and their family describe clumsiness in common daily activities. Disturbances in motor speed, fine motor control, and gait correlate with disease progression and appear to be better measures of duration of illness than chorea. Clumsiness may increase with deterioration of functional capacity (210).

**Reflexes.** Hyperactive reflexes occur early in up to 90% of patients, while clonus and extensor plantar responses occur late and are less frequent (206,210). Again, these latter phenomena are predominant in juvenile and advanced adult cases (210). Frontal release reflexes like snouting, sucking, or grasping typically accompany significant cognitive decline.

**Gait.** Gait disturbances ultimately result in severe disability (210). Subtle changes in gait may be observed early in the illness, including difficulty with tandem walking, sudden stopping on command, and turning (225). With more advanced disease, walking difficulties are more pronounced. As a consequence, patients experience frequent falls with significant associated morbidity and often ultimate confinement to a wheelchair.

**Speech.** Most patients display speech abnormalities (206,218), which are present early in the illness (226,227). Initially mild disturbance of clarity appears, which is aggravated by changes in rate and rhythm of speech as the disease progresses.

**Dysphagia.** Disturbances in swallowing generally occur later with progression of the illness. Initially, this may primarily affect intake of fluids but later will also affect intake of solids. Choking with aspiration secondary to dysphagia is a common cause of morbidity.

**117.7.1.4.2 Cognitive Disturbances. Subcortical Dementia.** A global decline in cognitive capabilities is ultimately present in all HD patients. While global measurements of cognitive function may be preserved (228),

a typical pattern of decline becomes apparent very early in the disease, including slowness of thought, altered personality, affective changes, and impaired ability to integrate new knowledge.

**Memory.** Memory impairment is common early in the disease and is often one of the patient's presenting symptoms (229). Visuospatial memory is particularly affected, involving visual retention (228), while verbal memory remains fairly preserved until late. For example, patients have difficulty reproducing geometric designs but may remember facts, words, or stories. Retrieval of information is impaired (230), but verbal cues, priming, and sufficient time may lead to partial or correct recall (231,232). Recall of recent and remote events is equally impaired (233). The learning and acquiring of new motor skills (procedural memory) is also affected in HD. In contrast to other amnesic syndromes, orientation to both time and place remains intact until late in the illness (234).

**Attention and Concentration.** Attention and concentration are affected early (228), resulting in easy distractibility by interfering stimuli. Difficulty performing sustained simple motor tasks such as gazing laterally, sticking out the tongue, or tightly closing the eyelids may be a manifestation of this distractibility, rather than motor disturbance. Problems with organizing, sequencing, and planning; inability to coordinate and initiate complex actions; and inability to maintain a mental set or organize cognitive strategies constitute other early impairments (229).

**Language and Related Functions.** Dysarthria, slowness, and lack of initiative interfere significantly with fluency and spontaneous speech (235), but semantic and syntactic structure, word finding, and speech comprehension remain intact until the final stages of the disease (226). Difficulties in writing and recognition of objects have been ascribed to defective nonlinguistic modalities, such as visuoperceptual analysis, attention and concentration, and overall cognition (235). In contrast, simple naming of daily objects, as tested in the Mini Mental State Examination, may remain intact until the latest stages of the disease (234). Expression and perception of the musical, tonal, rhythmic, nonlinguistic aspects of language (prosody), which are a function of nondominant hemisphere structures (analogous to those mediating language in the dominant hemisphere), are impaired in affected HD patients (236).

**Visuospatial Functions.** Specialized neuropsychological tests reveal impaired visuospatial abilities that may be quite prominent in the later stages of the disease. However, patients are oriented to time and place and able to dress themselves, and have no obvious spatial neglect until late in the illness. Clearly, in comparison to Alzheimer disease, visuospatial disturbances are relatively preserved in HD (220). Similarly, a patient's insight into his or her deteriorating cognitive abilities, which is absent in Alzheimer disease, remains intact.

**Psychiatric Disturbances:** Although psychiatric disturbances are as characteristic of the disease as motor and cognitive abnormalities, these appear less consistently and are not necessarily related to the severity of chorea or dementia (237).

**Mood and Affect.** Changes in mood and affect are common, ranging from anxiety and ill-defined irritability to prolonged periods of depression. Suicide is more common in patients than in the unaffected population (238). Manic or hypomanic episodes also occur with increased frequency. Affective syndromes may precede the first signs of motor impairment by many years and do not usually manifest for the first time until late in the illness (220).

**Behavioral Disturbances.** Apathy, aggressive behavior, sexual disinhibition, and alcohol abuse are other symptoms seen in HD patients. They may be either a manifestation of the progressive cognitive decline, or, alternatively, manifestations of the mood disturbances, especially if they are reversible and related to the premorbid personality.

**Delusions and Hallucinations.** Delusions are frequent, occurring in up to 50% of the patients with advanced disease. They may be seen in depressive or manic episodes or they may be isolated, and they are frequently paranoid in nature. In contrast, hallucinations are less common (206).

**117.7.1.4.3 Other Manifestations. Weight Loss.** Weight loss is one of the features of late HD. Clinical follow-up (239) as well as anthropometric studies with dietary assessment (240), all show that the vast majority of HD patients lose weight in the course of the disease.

**Sleep.** Sleep may be disturbed in advanced disease, with frequent nocturnal sleeplessness and reversal of the day-night pattern of sleep (241). Choreic movements disappear during sleep.

**Incontinence.** Approximately 20% of all patients are incontinent of urine and feces in the terminal phases of the illness, but early incontinence is rare (206). Choreatic contractions have been electromyographically recorded from perineal musculature in affected patients (242).

**117.7.1.5 Neuropathology of HD.** Atrophy of the caudate nucleus and the putamen (the neostriatum) is the most characteristic pathologic feature of the disease (243–245), yet the severity of neostriatal abnormalities is highly variable. In a series of 163 clinically diagnosed cases, 13 lacked macroscopically visible atrophy, while in 18 cases the caudate was extremely shrunken and the putamen markedly atrophic (243). Microscopically, the neostriatal atrophy is characterized by neuronal loss and gliosis (243), which again may be highly variable. Full appreciation of neuronal loss, however, can only be obtained by cell counting. In these instances, even in the absence of caudate abnormalities macroscopically, regional loss of up to 40% of the normal neurons may be found (246). Medium- and small-sized neurons, those expressing enkephalin and Substance P, which are the

most abundant classes in human striatum, disappear, while larger interneurons appear relatively preserved.

Macroscopically, the whole brain often appears atrophic, with narrowed gyri, widened sulci, and a reduction of brain weight, sometimes by as much as 400 g (247). Cortical atrophy with changes in neocortical architecture has been frequently reported (247,248). The normal layered architecture is preserved, but alterations occur in layers III, V, and VI (236,248), with IV possibly also involved. The thalamus, similar to most structures, may be reduced in proportion to the rest of the brain (247,249). In contrast to variable changes in other extrastriatal structures, the hypothalamic lateral nucleus is atrophied while other brainstem nuclei are generally intact (250). Gross cerebellar atrophy is rare (251).

Ultrastructural studies of the caudate may reveal abnormalities in the nucleus and nucleolus, the endoplasmic reticulum, ribosomes, the Golgi apparatus, mitochondria, and lysosomes. In affected neurons, both degenerative and regenerative changes can be observed. In Golgi stains of medium-sized spiny neurons, abnormal dendritic branching, elongation of distal dendrites, and alterations in spine densities were visualized (252). Gliosis particularly manifested by astrogliosis may also be prominent. The caudate is more affected than the putamen (243).

**117.7.1.6 Neurochemistry.** The earliest and most extensively affected neurons are the medium-sized spiny striatal neurons that express  $\gamma$ -aminobutyric acid (GABA) and enkephalin (Enk) or GABA and substance P (243,253,254). A decreased number of fibers immunoreactive for Enk and substance P was already observable in the brain of an asymptomatic individual at high risk for having inherited the HD gene (255). Medium-size and large-size neurons containing the enzyme NADPH diaphorase (recently identified as a nitric oxide synthase) remain intact (256). These neurons contain somatostatin and neuropeptide Y as their neurotransmitters and are localized in the striatal matrix, probably serving as interneurons. Another relatively spared group are large aspiny, acetylcholinesterase-containing, and locally arborizing interneurons.

**117.7.1.7 Neuroimaging. CT and MRI.** CT and MRI scanning can demonstrate striatal atrophy in affected patients, but appreciable atrophy was thought to usually appear after the appearance of chorea (454); however, more recent work has clearly demonstrated significant striatal atrophy prior to the onset of overt motor deficits in persons at risk for HD (257–259). In the absence of genetic confirmation, a scan showing caudate atrophy supports a diagnosis, but a normal scan does not exclude the diagnosis. Extrastriatal atrophy has also been found in HD patients. There is reduced cortical thickness in early to moderate HD patients (260–262). Other subcortical structures including the globus pallidus, accumbens, and amygdala have also been found to be atrophied (249). In addition to gray matter, white-matter atrophy

is also present in HD patients and can be seen very early in the disease process for known gene carriers (258). While all of the MRI data are intriguing, methodological differences must be considered when reviewing this data. The data concerning striatal (caudate and putamen) and white-matter atrophy are highly reproducible; however, some of the data concerning the cortical gray matter and subcortical structures are not consistent. These differences make it difficult to generalize between studies; therefore, further refinement and standardization are needed.

**Positron Emission Tomography.** PET using  $^{18}\text{F}$ -deoxyglucose demonstrates decreased glucose metabolism in the caudate nucleus that appears normal on CT or MRI scan, both in affected persons and in some persons at risk (263–265). In addition, PET studies using radioactive tracers to examine dopaminergic receptor binding (indicative of neuronal loss in the striatum) in HD patients reveal changes in binding that is sometimes associated with clinical manifestations of disease (266). PET scanning may be a sensitive method to detect early HD-related changes, particularly during the transitional clinical phase when a definitive diagnosis cannot yet be made. Several PET measures in patients in this transitional period (pre-HD) are abnormal, including dopamine receptor binding and glucose metabolism (267,268). The finding of caudate hypometabolism lacks specificity since significantly decreased caudate glucose metabolism has been demonstrated in other diseases of the nervous system including (269).

**117.7.1.8 Genetics of HD.** HD is inherited as an autosomal dominant trait. The mutation is found in a gene encoding the protein huntingtin. A summary of normal and mutant HD allele sizes is presented in Table 117–2. The gene is transmitted by parents of either sex to children of either sex. Each child of an affected parent has an even chance of inheriting the gene. In fact, HD is an archetypical dominant disorder. Clinical differences are apparent between heterozygotes and homozygotes, where homozygosity is associated with a more severe clinical course (270).

In the past, it has been repeatedly stated that HD is completely penetrant. However, it is now evident that penetrance depends on the severity of the genetic abnormality, and only a proportion of patients with between 36 and 41 CAG repeats may manifest within their expected lifespan (271). The exact frequency of nonpenetrance is uncertain, but, if the number of CAG repeats is closer to 36, a greater proportion of persons would not be expected to manifest signs of the disease in their lifetimes.

**117.7.1.9 The HD Gene.** A novel gene containing a trinucleotide CAG repeat that is expanded on chromosome 4 was described (272). This highly polymorphic CAG repeat, located in the 5' region of the huntingtin gene, has been shown to range from 10 to 35 in the general population, while it is expanded beyond 36 repeats in

**TABLE 117-2 Normal and Mutant HD Allele Sizes**

Allele Type	CAG Repeat Size	Comments
Normal	≤26	
Intermediate	27 to 35	<p>Individual is not at risk of developing symptoms of HD but may be at risk of having a child with an allele in the abnormal range (284).</p> <ul style="list-style-type: none"> <li>The risk of a child inheriting a “mutant allele” from a parent with an intermediate allele is dependant on a variety of factors, including the sex of the transmitting parent (the conversion of an intermediate allele to a mutant allele as a result of CAG expansion has only been observed when the parent contributing the allele is male), the DNA sequence surrounding the CAG expansion, and the size of the allele.</li> </ul>
Mutant	≥36	<p>Alleles with 36 or more CAG repeats are observed in individuals with HD.</p> <ul style="list-style-type: none"> <li>Reduced-penetrance alleles: 36–40 CAG repeats. An individual with an allele in this range may or may not develop symptoms of HD in his/her lifetime (271, 281, 284).</li> <li>Full-penetrance alleles: 41 or more CAG repeats. Alleles of this size are associated with development of HD in a normal lifetime.</li> </ul>

HD patients. The HD gene is located on chromosome 4p16.3, encompasses 67 exons, and spans over 200 kb (272). The HD gene lacks homology to any previously characterized gene and encodes a protein of 3144 amino acids with a predicted molecular mass of 348 kDa. Multiple homologs of the HD gene have been cloned, including the rodent homolog (273,274). The human and the mouse genes are 90% homologous, with a high degree of sequence identity in the 5′- and 3′ untranslated regions.

The huntingtin protein is expressed in many different cells throughout the central nervous system (CNS) as well as in cell lines from different somatic tissues (275–277). There is no particular enrichment of the protein product in the basal ganglia. Furthermore, there is no altered expression of the protein with the expanded repeat in HD patients (276,277). Thus, the pattern of expression of both the messenger RNA and the protein does not provide clues to the causes for selective neuronal death in HD.

Gene targeting strategies resulting in homozygous deletion of this gene from mice reveal that offsprings are not viable. Timed pregnancy studies revealed that these

mice die before 8.5 days of age, showing that this protein is crucial for normal development and particularly for normal gastrulation (278–280). Studies of animals with heterozygous deletion of this gene have revealed that they have abnormal behavior characterized by increased locomotor activity as well as some changes in cognitive ability. Furthermore, detailed morphometric studies have revealed that these animals have significant reduction of neurons in the subthalamic nucleus (279). These studies, as well as others, have demonstrated the HD gene is also important for maintaining normal neuronal integrity in the basal ganglia.

**117.7.1.10 Relationship between Trinucleotide CAG Repeat Length and Clinical Features of HD.** A significant correlation between the number of CAG repeats and the age of onset of HD has been demonstrated (281,282). This association was present irrespective of the mode of clinical presentation at time of onset. The number of trinucleotide repeats in the upper allele account for up to 70% of the variation in the age of onset (283). Repeat length, however, is not indicative of any other particular clinical phenotype as there is no independent association between any particular clinical feature of the illness and the number of repeats.

Is it possible to predict the age at which, in an individual, the signs and symptoms of HD will start? In the initial studies that examined genotype–phenotype correlations, the scatter around the regression curve was too large to make meaningful predictions for individuals (281,282). Many of these studies were, however, confounded by not including carefully ascertained at-risk persons with CAG expansion who are asymptomatic. One study including such persons showed that it is possible to use CAG size to predict with narrow confidence limits expected age of onset (283).

**117.7.1.11 Molecular Analysis of New Mutations.** New mutations causing HD have been proposed to be exceedingly rare, with the mutation rate estimated as the lowest for any human genetic disease (218). This may reflect that proof of a new mutation in HD is difficult, as prior criteria for identification of a new mutation have stipulated that parents of the sporadic case must have lived beyond the expected age of onset of HD without any manifestations of the disease, paternity of the sporadic case must be confirmed, and the disease should be transmitted to the offspring of the sporadic case.

The CAG repeat lengths in sporadic cases of HD and their families were assessed in order to learn more about the molecular events underlying new mutations for HD. In these families, the sporadic HD patient had a number of CAG repeats in the upper allele that was in the size range seen in patients with this disorder. In all families in which DNA was available from parents, the repeat length on one parental allele was found to be significantly greater than that seen in the general population (more than 29) but below the range seen in patients with HD (an intermediate allele [IA]) (284). The sex of origin of

the IA was determined by examining DNA from parents. In all families (16 of 16), preferential origin of the new mutation from the paternally derived allele was demonstrated. This would suggest that the paternal allele in the IA range is more likely to undergo significant expansion to a repeat length in the range seen in patients affected with HD (284).

#### 117.7.1.12 Insights into Pathophysiology of HD.

Several reports have highlighted a characteristic morphologic feature in many of the polyglutamine expansion disorders. Intracellular aggregates have been found in neurons of affected patients (285) and in murine (286) and in vitro models of HD (287–289). The specific compositions of these aggregates are unknown, but recent evidence showed that truncated polyglutamine fragments are associated with an increased frequency of aggregate formation. This raised the possibility that aggregates are in some way associated with cell death. Findings in human studies showed that aggregates are present in numerous cells in which cell death does not occur or occurs less frequently. This includes regions outside the cerebral cortex and basal ganglia in patients with HD, such as the cerebellum, and also regions outside the CNS, such as peripheral tissues including muscle and the pancreas. Similar observations were reported in animal studies in which mice express full-length huntingtin (290). These studies suggested that the aggregates are markers for toxicity and are not directly causative of neurotoxicity. In one study, Arrasate and coworkers monitored inclusion formation and cell death in vitro in individual neurons that had been transfected with mutant huntingtin and observed that neurons with inclusions had an increased likelihood of survival compared to neurons without inclusions. This supported the hypothesis that huntingtin inclusions are not pathogenic and may be neuroprotective (291).

An accumulating body of evidence implicates proteolytic cleavage of mutant huntingtin in the pathogenesis of HD. Several studies have shown that the N-terminal region of huntingtin is cleaved by different families of proteases, including caspases, calpains, and aspartyl endopeptidases (292–294). Findings from human and murine studies also demonstrate intracellular accumulation of N-terminal huntingtin fragments (295,296). Several in vitro studies have demonstrated that expanded N-terminal fragments of huntingtin cause enhanced cytotoxicity compared with normal N-terminal huntingtin fragments (289), and transgenic animals expressing truncated mutant huntingtin (exon 1) demonstrate widespread neuronal degeneration in the brain (286,297,298). Transgenic animals expressing an expanded N-terminal fragment of huntingtin containing exons 1 and 2 show no neurodegeneration, indicating that expression of an expanded N-terminal fragment of huntingtin is in itself insufficient to cause neurodegeneration and pointing to a differential effect of distinct N-terminal fragments on neurotoxicity. Additional studies are needed to further

elucidate the role of huntingtin cleavage and proteolysis in the pathogenesis of HD.

Excitotoxicity is a process by which excessive activity of the glutamate signaling pathway, particularly through the N-methyl-D-aspartate (NMDA) type of glutamate receptor, leads to abnormal intracellular calcium levels resulting in cell death. The involvement of excitotoxicity in the pathogenesis of HD was first suggested by rodent studies in which intrastriatal injections of kainic acid or quinolinic acid produced lesions that mimicked many of the neurochemical and histopathologic features of HD (299–301) and were associated with HD-like behavioral deficits (302,303). Subsequent human studies demonstrated enhanced expression of members of the glutamate signaling pathway in striatal medium-sized spiny neurons selectively lost in HD patients compared to the spared interneurons. These observations provided a possible explanation for the selectivity in neuronal loss and further implicated aberrant glutamate signaling in the pathogenesis of HD (304–306). Enhanced activities of NR1/NR2B-type NMDA receptors and mGluR5 receptors have been identified as a key contributor to HD pathology (307–309). Along with human and animal studies showing abnormal mitochondrial calcium handling, these observations give rise to a coherent, multifactorial model of mutant huntingtin-mediated disruption of calcium homeostasis as a cause of excitotoxicity and neuronal degeneration in HD (310).

**117.7.1.13 Predictive Testing.** Predictive testing for HD has been offered in different parts of the world for several years. Prior to the introduction of these programs, research protocols were developed to evaluate the psychological impact of receiving either an increased or decreased risk result (311,312). There was major concern that an increased risk result would precipitate catastrophic reactions such as emotional breakdown or suicide.

Short-term follow-up of participants in the Canadian Predictive Testing Program have revealed that predictive testing for HD may maintain or even improve the psychological well-being of at-risk individuals (312). Most individuals who receive a decreased risk result have shown improvement in psychological health, while the individuals who have received an increased risk result have not responded to predictive testing in the negative manner feared when predictive testing programs for HD were first developed. Despite the fact that both groups as a whole responded well to predictive testing programs, several individuals did have difficulties in adjusting to their new status. For those who received an increased risk result, there has been a new focus on physical symptoms with request for physical examination and the need for continued support and reassurance that DNA testing is not synonymous with diagnosis of illness (313). Though it was expected that some individuals might have difficulty coping with an increased risk result, a similar frequency of problems was not expected among

those receiving a decreased risk result. About 10% of the decreased risk group have had serious difficulties adapting to their new status. The major hurdle for these individuals appears to be the realization that they are facing an unplanned future.

The demand for predictive testing has been lower than expected in studies conducted prior to the advent of predictive testing (314). In addition, prenatal testing for HD is not a frequently chosen option (315).

Cloning of the gene for HD has had impact on the demand for and attitudes of at-risk individuals toward both predictive and prenatal testing. The demand for predictive testing has increased significantly. Hope for an effective therapy that did arise as a result of the cloning of the gene for HD is likely to further reduce the demand for prenatal testing (316). The long-term effects of predictive testing for HD are not known, and there is a continued need for longitudinal investment to examine the psychological and social effects of testing and to collect data that best predict responses to change in risk status.

**117.7.1.14 Management of HD.** Drug therapy for the management of HD is currently still limited to symptomatic treatment. The dopamine depleting drug tetra-benazine has recently been approved in the United States for treatment of the chorea of HD (317,318). Choreic movements can be partially suppressed by neuroleptics, while hypokinesia and rigidity may be ameliorated by antiparkinsonian agents. Psychiatric disturbances may react well to psychotropic drugs. Cognitive impairment is not amenable to drug treatment. Successful symptomatic treatment, however, does not always lead to a significant improvement of functional capacity. Therefore, an important part of management is to help the patient and the family to cope with the disease. Effective therapy to retard disease progression has not yet been achieved, although recent pathophysiologic insights suggest novel approaches.

It should be stressed that the contribution of nonpharmacologic approaches to the general well-being of HD patients is more important than medication. For those patients still living in the community, the close attention of family and friends, the family doctor, the social worker, or a public health nurse will be increasingly required. While there are obvious declines in functional capacity, patients with HD can in many instances remain in partial employment and fulfill domestic responsibilities until far into the illness. Premature withdrawal from these activities may further exacerbate the feelings of inadequacy and loss of power associated with the illness.

Attention should also be paid to the well-being of family members. Apart from possibly being at risk for HD, they also suffer from their daily burden of providing adequate care for the patient. Intermittent, temporary relief from this burden through respite care may encourage them to continue. A crisis at home is the most common reason for forced institutionalization of HD patients.

Many of these options will depend on the society in which the patients live. The advice, help, and expertise of the national lay societies, therefore, are indispensable in accumulating knowledge about the specific problems and opportunities for people with HD in their own country.

## 117.8 DIFFERENTIAL DIAGNOSIS: OTHER CHOREIC DISORDERS

### 117.8.1 Benign Hereditary Chorea (OMIM 118700)

Benign hereditary chorea (BHC) (also known as chronic juvenile hereditary chorea) is much rarer than Huntington disease. The earliest descriptions date from 1966 and 1967 but few series of patients and families have been described (319,320). BHC starts before the age of 5 in the vast majority of cases, although onset shortly after birth or around age 10 may occur. Males and females seem equally affected. The severity of the choreic movements may reach its maximum between ages 10 and 20 but then tends to decrease. Apart from choreic movements that may affect the limbs (both proximally and distally), the neck, and the face, not many additional features occur. Dysarthria is rare, while tremor has been described in a few families. Motor development may be somewhat slow, and some patients manifest clumsiness. The disease does not lead to dementia and, in adulthood, is non-progressive. Although some individuals were reported to have intellectual disability, the majority seems to be of normal intelligence and cognitive development. Similarly, psychiatric manifestations are not part of the usual clinical course. Other findings, such as hypospadias and minor digital abnormalities, have been found in single families and may be chance occurrences. Neuropathologic examination of the brain of one affected individual did not yield any specific abnormalities (321).

BHC is inherited as an autosomal dominant trait. A locus at 14q was found in 2000 and later confirmed (322), but genetic heterogeneity is likely (323). The gene at the 14q locus turned out to be the gene for TITF-1, a homeodomain-containing transcription factor essential for the organogenesis of the lung, thyroid, and the basal ganglia (324). This gene was part of a 1.2-Mb deletion in one family. As a second mutation, a single nucleotide substitution of intron 2 of the TITF-1 gene has been described (321).

### 117.8.2 Dentatorubral-Pallidoluysian Atrophy (OMIM 125370)

DRPLA is a disorder that received its name from its neuropathologic characteristics. The initial reports from 1946 described sporadic cases, but in 1982, Naito and Oyanagi described five Japanese families with multiple affected members and an autosomal dominant pattern of inheritance (325). The disease is more common (although

still very rare) in Japan than in other countries. In fact, only a few families have been described from outside Japan. Three clinical phenotypes are evident. The first is dominated by initial ataxia and subsequent choreoathetosis. The second was called the pseudo-Huntington type, with choreic movements and dementia, and only mild cerebellar ataxia. The third consists of progressive myoclonic epilepsy: initial myoclonic and generalized seizures with progressive mental deterioration. Different phenotypes may occur in one family, but cerebellar ataxia could be elicited to some extent in almost all cases. Onset ranges from 6 to 69 years, and death occurs between ages 20 and 75. Disease duration is approximately 10 years. Anticipation was noted in some families, with early-onset, associated with myoclonic epilepsy, and later-onset, with ataxia, dementia, and choreoathetosis.

In the course of the disease, multiple CNS neuronal systems degenerate, consistently including the globus pallidus (especially its lateral part), the subthalamic nucleus or nucleus of Luys, the cerebellar dentate nucleus, and the red nucleus (326). In addition, several other structures in the brainstem and spinal cord may be affected. Similar to HD, neuronal loss and gliosis constitute the main microscopic findings, with secondary demyelination of affected tracts.

DRPLA is caused by CAG expansion in a novel gene on chromosome 12 (327,328). CAG expansion is strongly correlated with age of onset. In one African American family, a disorder clinically similar to typical DRPLA but lacking myoclonic epilepsy and basal ganglia degeneration (Haw River syndrome) has been shown to be caused by similar CAG expansion in the same gene (329). Antibodies directed against the C-terminus of the DRPLA gene product detect a protein of approximately 190 kD (330). Consistent with what is known from other CAG repeat disorders (see earlier section on Huntington Disease), small, round immunoreactive intranuclear inclusions in both neurons and glial cells in various brain regions have been found. Electron microscopy showed that such inclusions are composed of granular and filamentous structures that consist of polyglutamine-containing aggregated protein fragments (326).

### 117.8.3 Neuroacanthocytosis (OMIM 200150)

The presence of acanthocytes in a peripheral blood smear may be associated with neurologic disease. For clinical purposes, two groups of patients may be distinguished. The first may be additionally characterized by low serum  $\beta$ -lipoproteins and includes Bassen Kornzweig disease (autosomal recessive abetalipoproteinemia), a form of hypobetalipoproteinemia (331), and the HARP syndrome (hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration) (332). A second group comprises those with normal serum  $\beta$ -lipoproteins and, apart from a few patients with Neurodegeneration

with Brain Iron Accumulation (NBIA, formerly Hallervorden-Spatz disease) (333), includes patients with neuromuscular and basal ganglia disease with or without the McLeod blood group phenotype. In this latter group, the disorder is called neuroacanthocytosis, chorea-acanthocytosis, familial amyotrophic chorea with acanthocytosis, or the Levine-Critchley syndrome, after the authors of the two original papers that first described the disease.

Neuroacanthocytosis is a slowly progressive neurodegenerative disorder affecting basal ganglia, peripheral nerves, and muscle. In a review of 19 sporadic and familial British cases, as well as 26 cases from the literature, Hardie and coworkers (334) found onset varying between 8 and 62 years, with a mean of about 32.5 years. Of these 45 patients, 8 were reported to have died between 7 and 24 years after onset of the disease (mean, 13.9 years).

The clinical manifestations may resemble HD. Mild cognitive impairment and psychiatric symptoms may manifest early in the disease. Dementia will develop in most patients, but early in the disease, frontal lobe dysfunction dominates. Personality changes, impulsive and distractable behavior, mood disorder, paranoid delusions, and obsessive-compulsive features may necessitate psychiatric help (335). Contrary to adult patients with HD, epilepsy occurs much more frequently than in the general population, with about half of the reported cases affected.

Choreic movements of the limbs and face are present in almost all cases; they usually start in the legs. Orofacial dyskinesia may lead to tongue and lip biting, offering a strong clue to the diagnosis; it may cause severe problems with speaking and swallowing. Apart from chorea, dystonia, parkinsonism, and tics may occur in the course of the disease. Vocalizations and, rarely, coprolalia may resemble that seen in Tourette syndrome. CT or MRI studies of the brain may reveal atrophy of the caudate nucleus. In addition, in a number of cases focal symmetrical abnormalities can be demonstrated in various parts of the basal ganglia that consist of hyperintense lesions in T2-weighted MRI sequences. These lesions may be found in the caudate, putamen, or globus pallidus, where they may resemble the “eye-of-the tiger” sign in NBIA.

The clinical feature that distinguishes neuroacanthocytosis from HD is the presence of neuromuscular abnormalities consisting of hypo- or areflexia of tendon reflexes and distal amyotrophy. Serum creatine kinase activity is elevated in the majority of cases, while nerve conduction studies will reveal reduced sensory action potentials in about 50% of cases. In contrast, motor nerve conduction studies generally will be uninformative, and electromyography will reveal denervation in only a minority of cases (334).

The neuropathology of neuroacanthocytosis is distinct. In the CNS, the caudate nucleus, the putamen, and the globus pallidus consistently show atrophy with marked neuronal loss and gliosis. The substantia nigra, the thalamus, and the motor neurons in the spinal cord may

atrophy (336,337). In peripheral nerves, axonal loss primarily affects the large diameter-myelinated fibers distally, with signs of regeneration after axonal degeneration, but unmyelinated axons may not escape destruction (334).

Neuroacanthocytosis shows a recessive pattern of inheritance in most cases. A genome-wide scan in 11 families from geographically different areas revealed linkage in all families to a 6-cM region at 9q21 (399). In these families, 16 different mutations were identified in a gene called CHAC (338). CHAC encodes an evolutionarily conserved protein, called chorein by Ueno and associates, that may be involved in protein sorting (338,339). Various groups have confirmed mutations in this gene as the cause of neuroacanthocytosis, thus establishing CHAC as the major gene associated with neuroacanthocytosis. It is important to realize, however, that X-linked neuroacanthocytosis associated with the McLeod phenotype may present a clinical phenotype that may resemble CHAC-associated neuroacanthocytosis very closely (340).

#### 117.8.4 Paroxysmal Dystonic and Choreic Movement Disorders: DYT8 (OMIM 118800), DYT9 (OMIM 601042), and DYT10 (OMIM 128200)

Although the dystonia and chorea of the different disorders as described in the previous paragraphs may wax and wane with emotion, fatigue, and other exogenous factors, these involuntary movements are still considered to present a more or less static movement disorder. In contrast, the so-called paroxysmal hyperkinesias or dyskinesias present short-lasting (minutes to hours) episodes of dystonia or chorea, often with an identifiable precipitating event, without any signs of movement disorder in between.

The term paroxysmal dyskinesia encompasses various disorders, such as “familial paroxysmal choreoathetosis,” “familial paroxysmal dystonic choreoathetosis,” “paroxysmal kinesigenic choreoathetosis,” and others (341). A clinically useful classification has been proposed by Demirkiran and Jankovic, who used as classifying factors the duration of the attacks, the inducing factor, and whether the attacks are primary (familial or sporadic) or secondary (342). The most important classifying criterion, in their opinion, is whether or not attacks are induced by voluntary movements. The resulting categories are kinesigenic, nonkinesigenic, and exertion-induced paroxysmal involuntary movements. A secondary subdivision can be made to take into account the duration of the attacks—lasting longer or shorter than 5 minutes.

DYT8 is associated with the classical phenotype as described by Mount and Reback in 1940 as paroxysmal nonkinesigenic choreoathetosis (343). Attacks are typically brief, lasting a few minutes to hours only, and are precipitated by coffee, fatigue, emotional stress, alcohol, or tobacco. The movement disorder starts within the first few years of life. The locus was ultimately mapped to

2q33–q33 (135,143,385). In affected persons from two unrelated families, missense mutations in the myofibrillogenesis regulator gene (MR1) were then identified. These mutations were absent in control subjects and caused Ala7Val and Ala9Val substitutions. These disturb interspecies-conserved residues and are predicted to alter the amino-terminal  $\alpha$ -helix of MR1. The MR1 exon containing these mutations (exon 1) was expressed only in the brain, a finding that explains the brain-specific symptoms of subjects with these mutations (344).

DYT9, at 1p, is an autosomal dominant form of paroxysmal choreoathetosis with episodic ataxia (345). As in DYT8, episodes are typically brief, and precipitating factors were also similar to those in DYT8. The gene responsible has not been identified.

DYT10 is familial dominant paroxysmal kinesigenic choreoathetosis. Attacks are precipitated by sudden movements, onset is later in life, duration of attacks is seconds to minutes, there is daily occurrence, and patients show good response to anticonvulsants. A locus was mapped to 16p11.2–q12.1 (346), but the gene is still unknown.

It has been suggested that, in all instances, ion channels are excellent candidate genes, as ion channel mutations play a role in many other paroxysmal neurologic disorders, such as hypo- and hyperkalemic periodic paralysis, episodic ataxias, familial hemiplegic migraine, and various forms of familial epilepsy syndromes.

#### 117.8.5 Huntington Disease–like Illnesses: HD-like 1 and HD-like 2

Several genetic disorders have been identified which closely resemble Huntington disease. A 192-nucleotide insertion in the region of the prion protein gene (PRNP) encoding an octapeptide repeat in the prion protein on chromosome 20 is responsible for HD-like 1 (347), an inherited disorder with chorea and dementia. HD-like 2 (HDL2) also bears striking resemblance to HD. The genetic mutation associated with HDL2 is a CTG/CAG trinucleotide repeat expansion within the junctophilin-3 gene (JPH3) on chromosome 16q24.3 (348). In the normal population, the repeat length ranges from 6 to 27 CTG/CAG triplets, whereas affected individuals have 41 to 58 triplets. HDL2 manifests in the third or fourth decade with characteristic features of chorea, dystonia, or parkinsonism and progressive cognitive deficits over approximately 20 years. Early signs include behavioral and personality changes with deterioration of social interaction. Intracellular inclusions immunoreactive for expanded polyglutamine repeats are seen in the brains of patients with HDL2 (349).

#### 117.8.6 Neuroferritinopathy

This disorder typically presents with involuntary movements in people 40 to 55 years of age. Symptoms of

extrapyramidal dysfunction, including choreoathetosis, dystonia, spasticity, and rigidity, sometimes showing acute progression but not associated with significant cognitive decline or cerebellar involvement, are present. MRI showed cavitation of the basal ganglia confirmed by brain pathology (350,351). The disorder was mapped by linkage analysis to 19q13.3, which contains the gene for ferritin light polypeptide (FTL). An adenine insertion at position 460–461 that is predicted to alter carboxy-terminal residues of the gene product was found (352). Brain histochemistry disclosed abnormal aggregates of ferritin and iron. Low serum ferritin levels also are seen. Brain histopathology shows widespread reddish discoloration of the basal ganglia. The globus pallidus contains abundant iron-positive, roughly spherical inclusions most of which are also positive for ferritin. Many iron- and ferritin-positive profiles are present throughout the forebrain and cerebellum. The number and overall size of iron/ferritin elements greatly exceeded those found in elderly.

### 117.8.7 Familial Tic Disorders: Gilles de la Tourette Syndrome (Oimim 137580)

A tic is a sudden, rapid, recurrent, nonrhythmic, stereotyped motor movement or vocalization. Tics have long been considered the major manifestation of Gilles de la Tourette syndrome (TS), but the recognition of a range of behavioral abnormalities, particularly obsessive-compulsive disorder (OCD) and attention-deficit disorder (ADD), as part of the disease spectrum has greatly advanced our understanding of the pathophysiology and genetics of the syndrome (353,354). The diagnostic criteria for TS as formulated in the revised fourth edition of the DSM (DSM-IV-R) are as follows:

1. Both multiple motor and one or more vocal tics have been present at some time during the illness, although not necessarily concurrently.
2. The tics occur frequently throughout a period of more than 1 year, and during this period there is no tic-free period of more than 3 consecutive months.
3. Onset is before age 21.
4. Other causes of tics have been ruled out.

TS is considered to be a lifelong disorder with onset at a young age, but in a retrospective cohort study, 50% of TS patients were asymptomatic by age 18 (355). Although formerly considered to be rare, it has become clear that the disease is more prevalent than expected, and that the apparent rates may depend on the extent of surveillance and access to care. A community-based study of pupils enrolled in schools in Monroe County, New York, yielded an estimated prevalence of 3 per 10,000, with males being nine times as often affected as females (356). A study using a large insurance claims database found that in Medicaid-insured children, the rate of diagnosis of TS per 1,000 was 0.53 (95% confidence interval [CI]

0.51–0.55), and 0.50 (95% CI 0.49–0.52) in privately insured children (357).

### 117.9 CLINICAL FEATURES

Usually tics are perceived as involuntary motor acts, but many patients indicate that they feel a tension or “urge” building up that can be relieved by submitting to the tic. Therefore, tics may be voluntarily suppressed for some time (seconds to hours).

Tics may be divided into simple and complex motor tics, and phonic or vocal tics. Simple motor tics involve simple motor acts such as eye blinking, head nodding, or shoulder shrugging. These movements are characteristically brief and jerky. In contrast, complex tics involve an array of movements that are always characteristic and reproducible for one individual over a limited period of time. For example, standing up and striking one’s upper leg, jumping, or patting objects within reach may constitute the phenomena of complex tics. Similarly, vocal tics may be simple and complex. Sniffing, grunting, or coughing are examples of the former, while coprolalia, echolalia, or the stereotypic utterance of words and sentences are examples of the latter. Although too many coprolalia may be the most remarkable and characteristic feature of the condition, its frequency is probably less than 10% (358).

Characteristically, the frequency and severity of tics will wax and wane over time. Over the course of a day, they can be aggravated by anxiety, stress, and fatigue, while relaxation or concentration on an enjoyable task may lead to amelioration, but fluctuations also may occur over a timespan of months. In fact, during certain periods, tics may be minimal. In addition, their form and content may change over time, with a tendency for simple forms to be replaced by complex ones.

In its severity, TS stands at the extreme of a spectrum of tic disorders (353). *Chronic tic disorder* displays either motor or vocal tics, but not both. *Transient tic disorder* lasts from 2 weeks to 12 months. Benign tics of childhood may be recognized for a brief period in childhood, typically lasting less than 1 year. Finally, isolated, mostly simple tics, may develop later in life. Many of these individuals with non-TS tics may nevertheless represent milder manifestations of the same disease, as the prevalence of non-TS tic disorder in relatives of TS patients is increased.

Obsessive-compulsive symptoms were identified by Gilles de la Tourette, and since then they have been recognized as part of the disease. Estimates of their prevalence have ranged from 30% to 90%, depending on the assessment instruments used and whether it was OCD or obsessive-compulsive symptoms that were looked for. OCD has a negative impact on quality of life in individuals with TS (359). One survey revealed that about 20% of the first-degree relatives of TS patients displayed obsessive-compulsive manifestations without tics; this

was particularly the case among women (360). Similarly, in twin studies, high concordance rates for TS and obsessive-compulsive symptoms have been reported, higher in monozygotic than in dizygotic twins (361). It was concluded that obsessive-compulsive symptoms form part of the disease spectrum of TS.

Although TS is considered a basal ganglia disorder, there is only indirect evidence that the disease is caused by pathology in the basal ganglia. Simple and complex tics (“Tourettism”) have been observed after organic brain disease (e.g. encephalitis lethargica), trauma, stroke, tumors, carbon monoxide poisoning, herpes encephalitis, syphilis, multiple sclerosis, or Huntington, Alzheimer, or Creutzfeldt–Jakob disease (362). Tardive induction of TS-like symptoms by neuroleptic medication (363), aggravation of symptoms by dopamine agonists, but particularly the suppression of signs and symptoms by neuroleptics (see later) link TS to disturbances in dopaminergic transmission. Up to now, however, PET studies with metabolites and ligands involved in dopaminergic transmission have failed to yield abnormalities in TS patients. As with tics, obsessive-compulsive manifestations may be part of basal ganglia disorders such as Sydenham chorea or Huntington disease. In general, obsessive-compulsive signs are partially responsive to drugs such as fluoxetine and fluvoxamine—selective serotonin reuptake inhibitors that imply a role for this indolamine in the pathophysiology of the disease, in addition to dopamine.

Not unexpectedly, the complex behavioral disturbances in TS may be associated with altered activities in areas outside the basal ganglia. A fluorodeoxyglucose PET study of the brains of TS patients showed relatively decreased metabolic rates in paralimbic and ventral prefrontal cortices (particularly in orbitofrontal, inferior insular, and parahippocampal regions), as well as in subcortical regions that included the ventral striatum (nucleus accumbens/ventromedial caudate) and the mid-brain. These changes were more robust and occurred with greater frequency in the left hemisphere. They were associated with concomitant bilateral increases in metabolic activity in the supplementary motor, lateral premotor, and Rolandic cortices (364,365).

Postmortem studies of TS patients are rare. In one case, calcifications around the third ventricle and the mesencephalic periaqueductal gray matter were found, consistent with the localization of postencephalitic lesions that may be associated with Tourettism (366). Another study found immunohistochemical evidence for a decrease in dynorphin staining throughout the brain. The absence of dynorphin-containing striatal fibers projecting to the globus pallidus particularly was noted, while fibers that contained substance P and Enk were intact. These results suggest that dysfunction of multiple structures and systems may be associated with TS (367,368). In a recent set of 5 cases examined using quantitative methods, a

higher total neuron number was found in the globus pallidus pars interna, with a lower neuron number and density observed in the globus pallidus pars externa and in the caudate nucleus (369). A more striking deficit was revealed by examination of interneuron populations: TS patients demonstrated a 50%–60% decrease of both parvalbumin and cholinergic interneurons in the caudate as well as the putamen (370). Both of these observations suggest abnormalities in neurogenesis or neural migration.

### 117.9.1 Genetics

Strong initial support for a genetic contribution to the etiology of TS came from twin studies as well as from family studies, but the study of the genetics of TS has always been confounded by variations in clinical presentations and incomplete penetrance. Dominant inheritance with incomplete penetrance has been often proposed as the mode of inheritance, but linkage analysis of single- and multiple multigenerational pedigrees has yielded disappointing results.

A recent review discusses in detail the current state of the genetics of TS (371). Although several mechanistically based candidate genes have been examined, none yet has withstood the test of replication. Genome-wide scans have been limited in scope, with the largest published so far including only 111 individuals. The most informative studies have been in families with high penetrance. In a pedigree with a large number of familial TS cases, L-histidine decarboxylase (HDC), an enzyme central to histaminergic neurotransmission, was identified (372). Mice with deletion of HDC exhibit increased sensitivity to stereotypic behaviors after treatment with dopamine agonists (373), providing what may be a useful model for examining the disorder. It is likely, however, that the genetic basis of TS is polymorphic, and larger numbers of familial and sporadic cases will be required to establish a complete picture of the genetics underlying the disorder.

### 117.9.2 Treatment and Management

Counseling, psychological support, and education of affected and nonaffected family members, teachers, and coworkers constitute major goals in helping the patient to cope with the condition. A child psychiatrist's expertise is often required in handling issues related to the child's psychological development and maturation.

TS is characterized by episodic alterations in intensity of the tics over the years. Sometimes, in periods of mild tics, medication can be avoided. Should drugs be required, a gradually escalating approach is preferred. Often, partial relief may be obtained with the alpha-adrenergic agent clonidine, or the benzodiazepine clonazepam. Neuroleptics are more effective at suppressing tics but carry a much greater burden of potential side effects.

Traditionally, haloperidol has been the first choice for treatment since its efficacy in treating TS was demonstrated in 1961. Adverse reactions to haloperidol—and, indeed, to every neuroleptic drug—include drowsiness and sedation, mood alterations, parkinsonian signs, akathisia, acute dystonic reactions, and tardive dyskinesia. It has been estimated that only one third of all TS patients who start on haloperidol will eventually benefit from it for sustained periods. Pimozide also been studied extensively, and although effective against tics it also carries a risk of cardiac arrhythmia. In recent practice, the use of the “atypical” neuroleptics, such as risperidone, has become more common but long-term follow up data on these is lacking.

Apart from attempts to control tics, one may want to modify obsessive-compulsive symptoms. For this purpose fluoxetine, fluvoxamine, and clomipramine may be beneficial. Amphetamine-like substances such as methylphenidate, and again clonidine, have been employed to suppress hyperactivity and ADD in children. Care should be taken with methylphenidate, as this drug may exacerbate tics.

### Biographies

**Dr West** graduated from Alma College in Michigan in 1999 and received a PhD in Molecular Neuroscience from the Mayo Clinic School of Medicine in the laboratories of Dr John Hardy and Matthew Farrer in 2003. He went on to complete a Postdoctoral Fellowships at the UCLA Neuropsychiatric Institute in Los Angeles in the laboratory of Nigel Maidment and in the laboratory of Ted and Valina Dawson at Johns Hopkins School of Medicine. He joined the Department of Neurology at the University of Alabama at Birmingham School of Medicine in 2007 as the John A. & Ruth R. Jurenko Research Scholar in Parkinson disease research. Dr West's laboratory in the Center for Neurodegeneration and Experimental Therapeutics focuses on discovering the biochemical and genetic basis of Parkinson's disease.

**Dr Gray** graduated from Alabama State University in 1997. She then received her PhD. in Molecular, Cellular, and Developmental Biology from Ohio State University with a focus on Developmental Neurobiology. Her post-doctoral training was obtained in the Brain Research Institute in the Semel Institute for Neuroscience and Human Behavior at the University of California, Los Angeles. She moved to the University of Alabama at Birmingham in 2008, and joined the Department of Neurology as an Instructor and the Dixon Scholar in Neuroscience. She is currently an Assistant Professor in the Department of Neurology and a member of the Center for Neurodegeneration and Experimental Therapeutics. Her work focuses on elucidating the contribution of astrocytes to Huntington Disease pathogenesis.

**Dr Standaert** graduated from Harvard College in 1982. He received his M.D. and Ph.D. degrees from Washington University in St. Louis. He completed a one-year internship in Medicine followed by a three-year Neurology residency at the University of Pennsylvania. He was appointed a Howard Hughes Medical Institute Physician Research Fellow, and completed a three-year research and clinical fellowship in Neurology (Movement Disorders) at Harvard Medical School and Massachusetts General Hospital in 1995, and subsequently joined the faculty at MGH. Dr Standaert is presently at the University of Alabama at Birmingham faculty as the John N Whitaker Chair and Professor of Neurology. He serves as Director of the Division of Movement Disorders, the Director of the APDA Advanced Center for Parkinson Research at UAB, and is the Director of the Center for Neurodegeneration and Experimental Therapeutics. He sees patients in a weekly clinic and oversees many clinical trials for new treatments of Parkinson's disease. He is a member of the Scientific Advisory Boards of the Michael J. Fox Foundation for Parkinson Research, the American Parkinson Disease Association, and the Bachmann-Strauss Dystonia & Parkinson Foundation.

### 118.1 RECESSIVE ATAXIAS CAUSED BY CATALYTIC DEFICIENCIES

A large number of hereditary ataxias appear to be caused by “inborn errors of metabolism”—a term used by Garrod in the early 1900s (1). Although the genes responsible for these diseases are only now being discovered, their genetic basis and relevant biochemical abnormalities have been appreciated for quite some time. Indeed, the dissection of metabolic pathways in the early half of the twentieth century has played an important role in suggesting candidate enzymes in gene-hunting strategies. This is in contrast to the degenerative ataxias, for which positional cloning, a more time-consuming process, was needed to identify novel genes encoding for the most part novel proteins whose functions are still to be unveiled.

Like most disorders resulting from catalytic deficiencies, the metabolic ataxias tend to be recessive, since half the complement of enzymatic activity in heterozygotes is sufficient for most metabolic pathways to proceed. Moreover, these pathways lie at the root of several housekeeping functions, so the resulting ataxia is just one component of a complex clinical phenotype. It is this clinical picture that usually betrays the underlying metabolic defect. The metabolic ataxias can be divided, yet again, into one of the two groups. The first group encompasses those ataxias that present intermittently when the biochemical abnormalities are at their worst; the second category is characterized by a more chronic and progressive ataxia induced by specific enzyme deficiencies (Table 118-1).

### 118.2 INTERMITTENT ATAXIAS

Of the group that present with an intermittent ataxia, the most common are the aminoacidurias resulting from deficits of urea cycle enzymes, and disorders of pyruvate and lactate metabolism. In all of these conditions,

affected infants usually display mental retardation and developmental delay. It is, however, important to distinguish between these subtypes since supportive measures differ.

Deficiency of any of the enzymes in the Krebs–Henseleit urea pathway is the most common metabolic cause of hyperammonemia and intermittent ataxia. Affected infants present with clumsiness, vomiting, and headaches. At the peaks of hyperammonemia, usually induced by stress or ingestion of proteins, infants display seizures, involuntary movements, and ptosis. Unfortunately, there is no treatment to reverse the underlying enzyme deficiency. Supportive therapy takes the form of hydration and dietary restriction of proteins. Inheritance of urea cycle deficits is autosomal recessive, with the notable exception of the X-linked and relatively common *ornithine transcarbamylase deficiency* (OTC) (Xp21.1). It is important to note that occasionally female carriers with OTC present with symptoms that are typically triggered by a protein-rich diet (2). In these symptomatic females, the attacks can come even in adulthood.

Ataxias seen in the aminoacidurias, such as *intermittent branched-chain ketoaciduria* and *isovaleric acidemia*, are usually diagnosed by the characteristic odor of the urine of these infants. *Hartnup* syndrome is another aminoaciduria that results in ataxia; this disorder results from a defect in renal and intestinal transport of amino acids (in particular, the neutral amino acids) rather than a defect of a metabolic pathway. Because of the associated niacin deficiency, features of pellagra (e.g. rash and mental confusion) are often seen. In contrast to the hyperammonemias resulting from urea cycle deficits, treatment of the aminoacidurias consists of a high protein diet along with nicotinamide supplementation. In 1997, a mouse mutant displaying several features of Hartnup disease was generated in an N-ethyl-N-nitrosourea (ENU) mutagenesis screen. This gene maps to mouse chromosome 7 (3). The first gene to unambiguously cause a Hartnup

**TABLE 118-1 Genetics of Inherited Ataxias with Known Enzyme Defects**

Disease	Locus	Enzyme/Protein Deficiency
<b>I. Intermittent ataxias</b>		
<i>Hyperammonemias and aminoacidurias</i>		
OTC deficiency	Xp21.1	Ornithine transcarbamylase
Citrullinemia	9q34	Arginosuccinate synthetase
Arginase deficiency	6q23a	Arginase
Arginosuccinaciduria	7cen-q11.2	Arginosuccinate lyase
Hyperornithemia-hyperammonemia-homocitrullinuria	13q14	Mitochondrial ornithine transporter syndrome
Hartnup disease	11q13	—
Isovaleric acidemia	15q14-q15	Isovaleric Acid CoA dehydrogenase
<i>Disorders of pyruvate and lactate metabolism</i>		
Pyruvate dehydrogenase complex	Xp22.2–p22.1 (most common)	E1- $\alpha$ subunit of PDH complex (most common)
Pyruvate carboxylase deficiency	11q13.4-q13.5	Holocarboxylase synthetase
<b>II. Progressive ataxias from metabolic insufficiency</b>		
Hexosaminidase deficiency-GM2 gangliosidosis	Genetically heterogenous	Hexosaminidase A, B or S isozymes (Tay–Sachs disease)
Niemann Pick	11p15.4-15.1	Acid sphingomyelinase
Niemann Pick type C	18q11-q12	NPC1
Cerebrotendinous xanthomatosis	2q33-qter	Mitochondrial sterol 27 hydroxylase
Metachromatic leukodystrophy	22q13.31-qter	Arylsulfatase A
Adrenoleukodystrophy	Xq28	Adrenoleukodystrophy protein
Abetalipoproteinemia	4q22-q24	Microsomal triglyceride transfer protein
Hypobetalipoproteinemia	2p24	ApoB
Ataxia with vitamin E deficiency	8q13.1-q13.3	Alpha-tocopherol transfer protein
Lesch–Nyhan syndrome	Xq26-q27.2	Hypoxanthine-guanine phosphoribosyl transferase
Wilson disease	13q14.3-q21.1	ATP7B protein
Ceroid lipofuscinosis	Several variants	Multiple gene products
X-linked ataxia, ichthyosis and tapetoretinal dystrophy	Xpter-p22.32	Arylsulfatase C
<b>III. Progressive ataxias associated with defective DNA repair mechanisms</b>		
Ataxia telangiectasia	11q2.3	ATM kinase
Xeroderma pigmentosa	Several variants	Multiple
Cockayne syndrome	Several variants	Multiple

syndrome in humans is SLC6A19 (mapping to 5p15), a gene that encodes a sodium dependent and chloride independent neutral amino acid transporter (4,5).

*Pyruvate dehydrogenase deficiency*, a less common cause of metabolic intermittent ataxia, is most often caused by a mutation in the E1- $\alpha$  subunit of the pyruvate dehydrogenase enzyme (Xp22.2–p22.1) (6). This condition is characterized by lactic acidosis, seizures, mental retardation, and spasticity. Recently, a zebrafish model of this enzymatic defect has been generated, and it should help in understanding how best to treat the metabolic sequelae of this syndrome (7). *Biotin-responsive multiple carboxylase deficiency* is another autosomal recessive infantile ataxia caused by a variety of mutations in the holocarboxylase synthetase (*HLCS*) gene at locus 21q22 and characterized by seizures, myoclonus, and nystagmus (8–10). A late-onset (juvenile) ataxia can also result from a defect in the biotinidase gene located

on chromosome 3p25 (11). Both the infantile and juvenile ataxic syndromes are responsive to high-dose biotin therapy.

Metabolic ataxias are usually diagnosed by screening biochemical tests when the neurological abnormalities are first noticed. Based on a positive family history, it is even possible to diagnose OTC deficiency (and several of the hyperammonemias) from blood samples taken in utero. Pyruvate dehydrogenase deficiency can, in addition, be corroborated by a relatively simple biochemical assay on cultured fibroblasts. Despite the identification of individual gene defects, genetic testing, at least at present, is impractical because of the large number of mutations in the relevant genes.

Apart from the supportive therapy of hydration and dietary restriction for many of the metabolic ataxias, there is yet no treatment for the underlying enzyme deficiency. If the liver is the site of enzyme synthesis, then

liver transplantation may be an option. Gene therapy for these diseases is still in its infancy (12–14).

### 118.3 PROGRESSIVE ATAXIAS FROM METABOLIC INSUFFICIENCY

A variety of etiologies underlie progressive ataxias induced by metabolic insufficiency. Unlike the intermittent ataxias, these diseases usually present in later childhood or adolescence, most likely because cumulative damage must reach a threshold before the clinical signs appear. The persistence of the biochemical abnormalities explains the progressive nature of the symptoms. Storage disorders predominate in this group of ataxias (comprising sphingomyelin lipidosis, metachromatic leukodystrophy, Krabbe disease, Niemann–Pick disease type C, X-linked adrenoleukomyeloneuropathy, and the genetically heterogeneous ceroid lipofuscinosis and hexosaminidase deficiencies (e.g. Tay–Sachs disease, Sandhoff disease—see Table 118-1 for a more comprehensive list, along with the relevant genetic defects). In each case, the clinical picture in conjunction with the histopathological findings or biochemical tests is telling: for instance, in the case of Niemann–Pick, one often sees foamy storage cells in bone marrow, and when accompanied by the typical supranuclear gaze palsy, the diagnosis is virtually certain. *Adrenoleukodystrophy* is often suspected when the X-linked inheritance is confirmed. Adrenoleukodystrophy is caused by defective beta-oxidation of fatty acids in peroxisomes. This leads to elevated levels of very long-chain fatty acids in the blood (a finding used for diagnosis) and accumulation of cholesterol esters of fatty acids and gangliosides in membranes of cells particularly in the brain and adrenal cortex; hence, the frequent accompaniment of adrenal insufficiency. Adrenoleukodystrophy is caused by a mutation in the adrenoleukodystrophy protein (ALDP) on Xq28 that belongs to the ABC family of transporter proteins (15,16). It is important to remember that because of variability in X chromosome inactivation patterns, a small percentage of females will show some of the symptoms in X-linked conditions. Unfortunately, there is no cure for the ataxias induced by storage defects, but there is now a growing list of ataxias for which specific measures can be taken to at least halt progression (Table 118-2). *Wilson disease* or *hepatolenticular degeneration* is probably the best known and is characterized by copper overload. Although the disease was described by Kinnier Wilson in 1911, the relevant gene *ATP7B*, encoding a copper transporting ATPase, was discovered relatively recently (17). The culprit gene maps to 13q14.3-q21.1. Because there are at least 25 different disease-causing mutations in a gene that occupies 80kb of genomic DNA, genetic testing is currently not possible and diagnosis rests on clinical tests, including the demonstration of Keyser–Fleischer corneal rings in slit-lamp examination and liver biopsy findings (18). Because Wilson's disease

is an eminently treatable ataxic syndrome, it should be suspected in any young patient (typically less than 40 years of age) with ataxia, especially when the ataxia is accompanied by other well characterized features of this syndrome. Treatment in Wilson's has a three-pronged strategy: 1. Reduction of accumulated tissue copper by the administration of copper chelators (such as penicillamine and trientine). 2. Reduction of copper absorption from the gut by oral zinc. Zinc induces metallothionein in enterocytes that helps chelate ingested copper that eventually is excreted in the stools as enterocytes turn-over. 3. Reduction of copper intake by avoiding foods rich in copper (for instance, shellfish, nuts, chocolates). With adherence to the treatment plan, patients generally respond well.

Ataxia with isolated vitamin E deficiency (AVED) is the name given to a group of autosomal recessive ataxic syndromes. This syndrome typically presents as a slowly progressive ataxia syndrome with neuropathy, sometimes with a phenotype virtually indistinguishable from FRDA (19,20). Some patients also develop retinitis pigmentosa (21,22). The most common genetic lesion is in the alpha tocopherol transfer protein TTPA encoded by the tocopherol transfer protein gene *TTP1* (8q13.1-q13.3) (AVED-MIM 277460) that is involved in the secretion of vitamin E from cells (23).

*Hypovitaminosis E* can also occur as part of abetalipoproteinemia, also known as *Bassen–Kornzweig disease* or *acanthocytosis* because of the presence of acanthocytes in peripheral blood smear evaluations. Characterized by hypocholesterolemia, hypolipidemia, and reduction of fat-soluble vitamins A, D and K, this ataxia is inherited in an autosomal recessive fashion. Patients often suffer from pigmentary retinopathy from the coexisting deficiency of vitamin A. The genetic defect is caused by mutations in the microsomal triglyceride transfer protein (MTP), resulting in an inability to form the apoB peptide of LDL, and VLDL (24). Recently, genetic defects that result in a similar ataxic syndrome have been identified in the apoB gene itself. In all these diseases, oral supplementation with vitamin E in high doses is effective in slowing down the progression. Therefore, it is important to test vitamin E levels in any chronic ataxic syndrome. Recently a mouse model for AVED has been engineered by deleting the gene encoding the mouse version of the alpha tocopherol transfer protein (25). This mouse model, like the human patient, responds to vitamin E therapy and should help in elucidating the cellular pathogenesis of this syndrome.

*Cholestenolosis* or *cerebrotendinous xanthomatosis* (CTX) is a relatively rare cause of progressive ataxia. Caused by any one of a variety of defects (missense, nonsense and frameshift) in the mitochondrial 27 hydroxylase gene (locus 2q33-qter), CTX is characterized by autosomal recessive ataxia, neuropathy, cataracts, and achilles tendon xanthomas (26). MRI reveals cerebral atrophy and evidence for demyelination. The diagnosis

**TABLE 118-2 Potentially Treatable Hereditary Ataxias**

Disorder	Metabolic Abnormality	Clinical Features	Treatment
Bassen–Kornzweig syndrome	Abetalipoproteinemia	Acanthocytosis, retinitis pigmentosa, fat malabsorption	Vitamin E
Ataxia with isolated vitamin E	Deficiency of alpha-tocopherol transfer protein	Progressive ataxic syndrome	Vitamin E deficiency (AVED)
Hartnup disease	Tryptophan malabsorption	Pellagra rash, intermittent ataxia	Niacin
Mitochondrial complex defects	Complexes I, III, IV	Encephalomyelopathy	Riboflavin, CoQ10, dichloroacetate
Multiple carboxylase deficiency	Biotinidase deficiency	Alopecia, recurrent infections, variable organic aciduria	Biotin
Pyruvate dehydrogenase deficiency	Block in energy metabolism	Lactic acidosis, ataxia	Ketogenic diet, chloroacetate
Refsum disease	Phytanic acid, alpha hydroxylase	Retinitis pigmentosa, cardiomyopathy, hypertrophic neuropathy, ichthyosis	Dietary restriction of phytanic acid
Urea cycle defects	Urea cycle enzymes	Hyperammonemia	Protein restriction, arginine benzoate, alpha ketoacids

is confirmed by elevated serum cholestanol in the face of normal cholesterol. Treatment with chenodeoxycholic acid appears to halt progression of the disease. In addition, statins help in delaying atherosclerosis in these patients (27,28).

*Refsum disease* is yet another treatable ataxia caused by an enzyme deficiency, in this case a deficiency of phytanoyl-CoA hydroxylase with the culprit gene mapping to locus 10pter-p11.2. Refsum disease should be suspected when autosomal recessive ataxia presents with the triad of ichthyosis, retinitis pigmentosa and neuropathy (29,30). Patients with this disease cannot degrade phytanic acid due to a deficient activity of phytanoyl-CoA hydroxylase (PhyH) (with mutations in the gene encoding this protein), a peroxisomal enzyme catalyzing the first step of phytanic acid alpha-oxidation (31). Since toxicity in this disease is a result of the elevation of phytanic acid, the disease is preventable by avoiding the food containing this substance or its precursors.

There are a set of ataxias that are caused by enzymes that involve in DNA repair mechanisms. Because they do not result in metabolic ataxias, we have discussed them in a separate section below.

## 118.4 PROGRESSIVE ATAXIAS THAT ARE NOT BECAUSE OF METABOLIC DEFECTS

### 118.4.1 Friedreich Ataxia (FRDA, Spinocerebellar Ataxia-MIM 229300)

Friedreich ataxia (FRDA) is the most common autosomal recessive spinocerebellar ataxia, with a prevalence rate of 1 to 2 per 100,000. In the typical case, symptoms begin in late childhood or adolescence. The neurological phenotype is characterized by the cerebellar features of ataxia, scanning speech and nystagmus. In addition, eye movements tend to be sluggish, the gait is disorganized

and lurching, and patients demonstrate signs of motor and sensory neuropathy. Because of motor neuropathy, especially in the later stages of the illness, the distal extremities become weak and wasted while sensory neuropathy causes loss of vibration sense and proprioception. Early evidence for sensorimotor neuropathy can be elicited clinically by absent ankle reflexes and impairments on electrophysiological tests. These constitute the core features of the diagnosis, formalized in Harding's essential criteria with the additional proviso of onset before the age of 25 with most patients wheelchair bound around 15 years after the onset of symptoms (32). Other noteworthy neurological features include bladder incontinence and deficits of the special senses that can further decrease the quality of life. Vision is often mildly affected by optic atrophy, which typically causes impaired color vision. Deafness is a relatively rare accompaniment (it occurs in less than 10% of patients) and results from degeneration of cochlear neurons. Despite widespread neurological involvement, intellectual deficits are not all that common. Among the pyramidal features, extensor plantar responses are common, and sometimes spasticity can be observed. Rarely, extrapyramidal involvement in the form of choreiform movements may be seen. The most common pathological findings include degeneration of the posterior columns, spinocerebellar tracts and large sensory neurons of the dorsal root ganglia.

Besides involvement of the nervous system, patients with FRDA often have musculoskeletal abnormalities. Most patients display some degree of scoliosis or kyphoscoliosis and pes cavus. Cardiac pathology is another hallmark and usually results from muscular subaortic stenosis and hypertrophic cardiomyopathy. In the early stages of the disease, however, a wide range of abnormal EKG findings have been observed: T-wave abnormalities, deep Q waves, low QRS complexes, and the more obvious heart-block. In the later stages, a dilated form of cardiomyopathy with wall motion abnormalities replaces

the earlier hypertrophic picture. At a pathological level, there is cardiomyocyte hypertrophy, fatty degeneration associated with interstitial fibrosis, and eosinophilic and lymphocytic infiltrates. Although there is variability in the progression of the disease, the mean age of death is in the fourth decade (33). Death occurs because of cardiac complications or bulbar dysfunction that results in an inability to protect the airway. As in AT, approximately one fourth of the patients with FRDA develop glucose intolerance and diabetes that increases morbidity.

Since discovery of the gene and the availability of genetic testing, we are beginning to learn more about the less typical FRDA phenotypes. For instance, FRDA can present as early as infancy and should be suspected when delay in achieving motor milestones is associated with skeletal abnormalities. This early-onset phenotype tends to be associated with a worse prognosis than typical FRDA. Surprisingly, FRDA can also present much later in life, even beyond the age of 40, in a so called “very late-onset FRDA” (34,35). Some of these atypical features are found in shorter repeats (36) or in compound heterozygotes where one allele has a pathogenic GAA allele, while the other has a point mutation (missense, nonsense, or intronic) (37–40). Since several of the cardinal features of FRDA are milder in this instance, with a preservation of reflexes, these patients were bracketed into a separate category in the pregenetic era: “autosomal recessive ataxia with preserved reflexes.”

In the past, the diagnosis of FRDA was primarily a clinical one, resting on the aforementioned signs and symptoms and supported by only a few ancillary tests. Electrophysiological testing provides additional evidence for motor and sensory axonal neuropathy, whereas EKG findings present supportive evidence relating to the cardiac manifestations of the disease. MRI scans in FRDA often show evidence for spinal cord and cerebellar (particularly vermal) atrophy. In the spinal cord, atrophy affects the posterior columns, the spinocerebellar tracts and dorsal root ganglion (41). Today, the only diagnostic test is, of course, genetic, and testing should be performed in all recessive and chronic ataxic syndromes, based on what we know of their broad phenotypic spectra.

FRDA is caused by a GAA repeat expansion in the first intron of the gene called *frataxin/FXN* or X25. This gene is located on chromosome 9q13 (42). Most normal individuals carry alleles ranging from 7 to 34 GAA repeats, while patients with the disease have alleles with a tract of over 100 repeats. Tract sizes that vary between 34 and 100 do not result in disease but are further divided, based on whether or not they are interrupted by non-GAA repeats. If interrupted, they are considered nonpathological, because the interruption stabilizes the repeat against expansions in subsequent generations. On the other hand, uninterrupted repeat tracts with 34 to 100 GAAs are considered to be premutations, since without the stabilizing influence of the interruption, they can expand to over 300 repeats in just a single generation (43).

The unstable repeats tend to expand in paternal transmission and can expand or contract in maternal transmission. As mentioned earlier, because of the recessive nature of the disease, with a requirement for two expanded alleles, there is no anticipation. Nonetheless, disease severity and onset of disease correlate with repeat length. This is not just confined to the neurological phenotype, but also holds true for the glucose intolerance and the skeletal and cardiac abnormalities (44,45).

As might be expected from its recessive genetics, FRDA is caused by a loss of function of the gene product, frataxin. The intronic repeat expansion results in a reduced expression of the messenger RNA encoding this 210 amino acid protein. The precise mechanism is still unknown. Nevertheless, it has been speculated that the expanded repeats result in a higher order DNA structure that stymies transcription (46). That FRDA, caused by a loss of function mechanism, is supported by the observation that a Friedreich phenotype can also be seen in patients carrying only one expanded allele of frataxin, provided that their second allele is inactive due to a point mutation (14). This situation might be more common than currently recognized, since most current genetic tests search for expansions and not for other types of mutations.

Recent research has focused on delineating the function of frataxin and explaining why its loss should result in such widespread and profound pathology. It appears now that frataxin is a mitochondrial protein, expressed at particularly high levels in tissues undergoing degeneration such as the brain, heart, and pancreas (35,47,48). From studying the yeast frataxin homologue (YFH1), it appears that this protein is involved in the normal efflux of iron from mitochondria (49). Iron accumulates in the mitochondria, which in turn might disrupt mitochondrial respiratory chain function and cause susceptibility to oxidative stress (50). Frataxin has also been demonstrated to function as an iron chaperone protein for aconitase, an enzyme essential in the citric acid cycle (51). In humans, iron deposits have been found in the myocardium of FA patients (52). This raises the intriguing possibility that we may be able to employ chelating agents and antioxidants to reverse pathology (53).

Mouse models of FRDA are providing clues to pathogenesis (reviewed in (54)). Frataxin knockout mice are embryonic lethal, while heterozygosity for the frataxin null allele shows no pathological phenotype. These results suggest that frataxin expression associated with expansion mutation is critical for survival and haplo-insufficient levels of frataxin can completely prevent deleterious consequence (55). Conditional animal models have been generated to reproduce certain morphological and biochemical features observed in patients with FRDA, including cardiac hypertrophy without skeletal muscle involvement, large sensory neuron dysfunction without alteration of small sensory and motor neurons, and deficient activities of complexes I through

III of the respiratory chain and of the aconitases, an enzyme essential in the citric acid cycle (reviewed in (54)). Another useful mouse model is a humanized GAA repeat expansion mouse model that was generated by combining the constitutive knockout model with the transgenic expression of a yeast artificial chromosome (YAC) carrying the human locus. These repeat expansion mice show oxidative stress and progressive neuronal and cardiac pathology (56).

A phenocopy disease of Friedreich's ataxia without mutations in the *FXN* gene has been described in a few familial cases (57,58). In one family, this disease has been linked to chromosome 9p23-p11 and has been called FRDA 2 (MIM 601992).

Current therapy aims at reducing oxidative stress that can be followed by markers of oxidative injury (59,60). These medications include antioxidants such as coenzyme Q10 and vitamin E. The the best predictor of a positive clinical response to CoQ(10)/vitamin E therapy appears to be pretreatment decreased serum CoQ10 levels often seen in FRDA. Studies to date suggest that both low- and high-dose CoQ10/vitamin E therapies were equally effective in improving ICARS scores (61).

Another promising agent appears to be the free radical scavenger, idebenone, a short-chain analog of coenzyme Q10 (Reviewed in Reference (62)). In initial studies, idebenone at 5mg/kg and 10mg/kg/day demonstrated improved cardiac function with no significant benefit on the progression of ataxia (62). It appears that higher doses of idebenone (up to 60 mg/kg/day) are well tolerated and provide some neurological benefit with an improvement in parameters that contribute to activity of daily life (ADL) (63).

Recent experiments suggests that expansion of intronic GAA repeats causes *FXN* silencing by causing chromatin changes in particular histone hypoacetylation that correlates with transcriptional repression (64). Treatment with a histone deacetylase (HDAC) inhibitors in mouse models appears to restore frataxin levels in the nervous system and heart (65). Whether these agents will be successful in human patients is clearly the next step that will depend on exploring this possibility in well-designed clinical trials.

Iron chelation has typically not been used because despite some evidence for iron accumulation in mitochondria in some brain regions, there is normal or even mildly reduced levels of plasma iron. There are some promising results with using the chelator deferiprone (20 to 30mg/kg per day in two divided doses) in combination with idebenone. Deferiprone unlike idebenone has the potential of significant side effects (has been reported to cause fatal agranulocytosis), and its use is confined to clinical trials (53).

Unfortunately, none of these treatments have a major impact on disease progression. Yet much can be done for each individual patient, and when treatment is instituted by a team of medical personnel, neurologists,

occupational and physical therapists are in the best position to address issues relating to the symptomatic treatment for spasticity, surgical correction of scoliosis, exercises to help with loss of balance, and poor motor control (along with recommending devices to assist in activities of daily living); cardiologists and endocrinologists can help with the management of cardiomyopathy and diabetes; finally, like any of the other chronic neurodegenerative syndromes, most patients require genetic and psychological counseling.

## 118.5 PROGRESSIVE ATAXIAS ASSOCIATED WITH DEFECTIVE DNA REPAIR MECHANISMS

Although caused by known enzymatic defects, these autosomal recessive disorders are caused not by derangements in intermediary metabolism but by a specific inability to repair damaged DNA. As might be expected from such a threat to the genome, all of these closely related conditions—ataxia telangiectasia, xeroderma pigmentosum, and Cockayne syndrome—are characterized by wide-ranging deficits.

*Ataxia telangiectasia* (AT; Louis Bar Syndrome-MIM 208900) is the most common of the three. The disease manifests in early childhood as growth retardation, hypotonia, and diminished reflexes. As the disease progresses, children develop ataxia along with oculomotor apraxia, choreoathetosis, nystagmus, and peripheral neuropathy (66). The hallmark telangiectases are most often seen in the conjunctiva of the eyes and in exposed areas of the skin (typically the nose, ears, and neck), and usually develop by the age of seven. Sometimes, other skin lesions such as vitiligo or hypopigmented spots can also be seen. In the absence of telangiectases, either early in the course of the disease or in atypical cases, AT can be difficult to distinguish clinically from other chronic ataxic syndromes (67). If ataxia develops early, it may be misdiagnosed as an ataxic variety of cerebral palsy, particularly since mental retardation is not a feature; when the onset is delayed, it is most often mistaken for FRDA. Dystonia and choreoathetosis occur in the majority of patients especially as they grow older. Patients often have an element of facial weakness that leads to poor facial expression and drooling, while the peripheral neuropathy leads to decreased vibration and position sense and poor stretch reflexes (68). Another characteristic feature is oculomotor apraxia that is best elicited by asking the patient to initiate saccades. Patients have problems with this task, and to compensate, they tend to thrust their head or blink excessively while initiating saccades (69).

Apart from neurodegeneration, growth retardation and gonadal dysfunction, AT is also characterized by a predisposition to cancer and immune function defects. The malignancies typically affect the lymphoreticular system (lymphomas, leukemias, and Hodgkin disease), but there is also increased risk of cancers of the breast,

skin, and stomach. Infections resulting from deficiency in both cellular and humoral immunity typically affect the airway and are often life-threatening. Other features of AT that contribute to morbidity include glucose intolerance because of peripheral insulin resistance and the associated complications of diabetes.

Of diagnostic importance are the low levels of IgA and IgE, a testimony to the defects in humoral immunity. Other humoral deficits that have been observed include elevation of immunoglobulins M, G1, and G3 and deficiency of immunoglobulins G2 and G4 concentrations.

In addition, deficient cellular immunity is reflected in anergy to intradermal injections of test antigens. Another helpful diagnostic feature seen in more than 90% of patients is the elevation of serum alpha-fetoprotein levels and carcinoembryonic antigen (CEA). Identification of the *AT* gene has now led to genetic testing, but diagnostic features clearly aid in pointing physicians to the right diagnosis. Moreover, since the cloning of the *AT* gene, it is becoming apparent that abnormalities in even one copy of the gene predispose heterozygotes to an increased incidence of cancer (particularly of the breast). Thus, although ataxia is a recessive trait, heterozygotes are clearly not normal, at least from the standpoint of predisposition to malignancies.

Both the central and peripheral nervous systems are involved in AT. The central nervous system pathology is more severe and is characterized by cerebellar atrophy, in particular, loss of Purkinje cells and granule cells with some loss of basket cells. In addition, patients sometimes show degeneration of the dentate and olivary nuclei, the substantia nigra and neurons of the oculomotor complex, pretectal nuclei, and hypothalamus. Pituitary cells often have enlarged or dysplastic nuclei. The spinal cord also demonstrates abnormalities, typically denervation of the posterior columns of the spinal cord, degeneration of the anterior horn cells, and decreased numbers of satellite cells, whereas the peripheral nervous system involvement is characterized by malformed nuclei in Schwann cells (70). In line with deficits in the immune system, the thymus is characteristically hypoplastic, with fewer lymphocytes and absent Hassall corpuscles.

AT is a difficult disease to treat and has an especially poor prognosis because of its multisystem involvement. There is no specific treatment for the ataxic syndrome or the progressive cerebellar neurodegeneration. For the ataxic symptoms, therapeutic agents like amantadine, fluoxetine, and buspirone can be tried. The tremors may respond to gabapentin, clonazepam, or propranolol. L-DOPA and anticholinergics may be tried to improve any associated extrapyramidal dysfunction (71). Infections should be aggressively treated with antibiotics and simple maneuvers such as postural drainage of lung abscesses. Diagnostic tests involving X-rays and ionizing radiation should be kept to a minimum, to avoid causing iatrogenic somatic mutations and malignancies. Treatment of malignancies, when they almost invariably occur,

is complicated by the fact that these patients cannot tolerate conventional doses of radiation therapy. Despite the best supportive measures, most patients die in their third decade. More recently, less severe variant forms of AT have been described, where neurological features of AT may occur with minimal immunodeficiency, telangiectasias, cancer, and sinopulmonary infections (72,73). These individuals have decreased chromosomal instability and cellular radiosensitivity that translates into a later onset and slower progression. In these variants, some ATM activity is preserved, which explains the less robust phenotype.

The *AT* gene was mapped to chromosome 11q22.3 in 1988, and the gene was finally cloned in 1995 (74,75). The gene product, ATM or ataxia telangiectasia mutant, is a 370-kDa protein (76) ubiquitously expressed in all tissues of the body. This protein belongs to a family of important protein kinases called inositol-3 kinases. The ATM kinase appears to play a key role in stalling cells at cell cycle checkpoints in response to DNA damage. This supervisory function of ATM offers the cell an opportunity to repair the damage rather than bequeath inappropriate genetic information to daughter cells. In the absence of this checkpoint, cells build up somatic mutations and thus increase the risk of cancer. The major mechanistic steps in ATM pathogenesis are only now being unraveled. It appears that in response to double-stranded DNA damage, the ATM kinase directly interacts with and phosphorylates the tumor suppressor protein p53 (77). Phosphorylated p53 serves as a transcriptional activator of genes that cause cell cycle arrest or apoptosis. In the absence of ATM, p53 is no longer phosphorylated and therefore cannot prevent the cell from moving into the next phase of the cell cycle. More recently, ATM has been shown to phosphorylate another tumor suppressor, Bcr1, one of the genes implicated in breast cancer (78). This interaction may explain how ATM predisposes patients and heterozygotes to breast cancer and why the body is so sensitive to ionizing radiation and radiomimetic chemicals. It also explains why the immune system is affected since breakage of double-stranded DNA is the mechanism by which diversity of antigen receptors is produced by lymphocytes. None of these molecular explanations explain why the nervous system, specifically the cerebellum, is affected in this syndrome. It is possible that ATM is crucial for surveying the genome for DNA damage in neurons that suffer from significant oxidative stress (79). Recent engineered mouse models of the disease promise to increase our understanding of the molecular mechanisms of pathogenesis. Disruption of the mouse version of the gene recreates the neurological phenotype, growth retardation, and defects in the immune system, apart from the sensitivity to radiation (80). This is an exciting area of scientific research at the confluence of tumor biology, cell cycle research, and neurodegeneration (81,82). It is also possible that deficiency of ATM contributes to neurodegeneration in pathways

distinct from its role in DNA damage. For instance, there is evidence to suggest that cytoplasmic ATM is involved in vesicular/protein transport (83).

The most immediate benefit of cloning the gene has led to diagnostic testing and describing unusual clinical variants as alluded to earlier. The *ATM* gene is itself very large, with 66 exons spanning 150kb of genomic DNA (84). Using a combination of techniques, it is estimated that more than 95% of affected individuals can be identified by genetic testing (85). Developing diagnostic test has been a challenge, given the variety of mutations found: it is estimated that truncating mutations account for about 85% of mutations, while point mutations are responsible for the rest (32). Furthermore, the majority of patients are compound heterozygotes.

A disease very similar to AT, known as the Aicardi variant, was in the past separated from AT by the lack of telangiectasia and severe limitation in vertical eye movements. This disease is now known to share the same genetics as AT. There are a few disorders that closely mirror AT but result from defects in genes other than *ATM*. The disease that resembles AT the closest is called ataxia telangiectasia-like-disorder (ATLD-MIM 604391). ATLD is caused by a mutation in a gene (*hMRE11*) encoding a protein involved in the DNA repair complex of which AT is another component (86). Patients with ATLD have a slowly progressive ataxia and ocular apraxia, but do not develop tumors. Furthermore, they did not have telangiectasia, raised alpha-fetoprotein, or reduced immunoglobulin levels (87).

Xeroderma Pigmentosa and Cockayne syndrome are two other syndromes that have deficiencies in DNA repair pathways and can be associated with ataxia.

*Xeroderma pigmentosum* (XP) has an incidence of approximately one in a million. This disease is characterized by a wide variety of cutaneous lesions from mild freckling to xerosis, erythema, bullae, telangiectasia, actinic keratosis, and skin malignancies. Most of these lesions occur around the eyes and eyelids. The eyes also show an increased incidence of keratitis, opacification of the cornea, iritis with synechia formation, and malignant melanoma of the choroid. The neurological features of xeroderma pigmentosa consist of progressive cognitive decline, sensorineural deafness, peripheral neuropathy and choreoathetosis. As with AT, XP is characterized by an increased risk of neoplasms (88). Oral administration of retinoic acid has been shown to be helpful in preventing skin cancer (89).

At a molecular level, XP constitutes a genetically heterogeneous group of disorders characterized by defects resulting in excision repair abnormalities (90). There are several complementation groups based on functional studies using fibroblasts derived from human patients. Patients in the same complementation group have a similar constellation of symptoms with variable neurological involvement that can range from severe to none at all. In addition, ultraviolet-sensitive Chinese hamster cells have

been instrumental in identifying genes involved in excision repair. Unfortunately, because some of these genes were named by both of these methods, there is some redundancy in the nomenclature.

*Cockayne syndrome* (CS) is a rare disorder (91). Although the clinical phenotype shows some overlap with XP with deafness and ataxia, patients with CS also show retinal degeneration and early ageing without displaying a tendency to develop cancer. Pathologically, there is evidence for demyelination in the central nervous system, along with basal ganglia calcification, both of which are detected in imaging studies. Like XP, CS is genetically heterogeneous, with several complementation groups. In fact, there are a few patients with a mixed XP-CS phenotype. The key defect in most cases appears to be insufficiency of transcription, or transcription-translation coupled repair, a phenomenon that pertains to excision repair of DNA that must precede the transcription of active genes (92). Mouse models of XP and CS have been developed; importantly, when crossed, they have a synthetic phenotype, suggesting yet again that these proteins are in the same genetic pathway (93).

Another set of diseases that mimic AT are the ataxia-ocular apraxia syndromes of which there are at least two: AOA1 and AOA2. AOA2 has also been called spinocerebellar ataxia of the recessive type 1. Other rarer ataxias that are being identified are being termed SCAR with numbers given in the order of locus identification (reminiscent of the autosomal dominant spinocerebellar ataxias described later in the chapter).

Ataxia-ocular apraxia type 1 (AO1; Early-Onset Ataxia with Ocular Motor Apraxia and Hypoalbuminemia-MIM 208920) (mapping to 9p 13.3 (94,95) is an autosomal recessive ataxia caused by mutation in the aprataxin (*APTX*) gene causing. Initially described in Japanese families, AOA1 presents with gait imbalance and dysarthria. These patients then progress over a few years to develop pronounced ataxia and ocular apraxia. Areflexia, dystonia, choreoathetosis, sensory and motor neuropathy, mental retardation, and retinal/macular lesions (picked up by fundoscopic examination) can all accompany the core clinical picture of ataxia and ocular apraxia. In addition, patients often develop hypoalbuminemia and hypercholesterolemia. AO1 is caused by a mutation in a histidine triad/zinc finger protein, called aprataxin, a protein involved in DNA single-strand break repair (96). Several mutations have been described including frameshift, nonsense mutations, and missense mutations with many patients being compound heterozygotes (96). Coenzyme CoQ10 has been found to be decreased in muscles of some patients with AO1, with some improvement with oral supplementation (97,98).

Ataxia-Ocular apraxia type 2 (AO2; mapping to locus 9q34) is another recessive ataxia characterized by unsteady gait, cerebellar atrophy, ocular apraxia, and a sensory-motor neuropathy. AO2 has more recently been called Spinocerebellar Ataxia, autosomal Recessive Type 1

(SCAR1-MIM 606002). But there are a few distinguishing features: this disease typically has a later age of onset, a less common ocular apraxia (only 50% of AO2 patients display ocular apraxia) and high levels of serum alpha-fetoprotein, creatine kinase, and gamma globulin with normal serum albumin and cholesterol (99). Patients may also show evidence of executive dysfunction on neuropsychological testing (100). At a molecular level, AOA2 is caused by mutations in the *SETX* gene, which maps to chromosome 9q34 (101). This gene encodes the protein, senataxin, which is a member of the helicase family of enzymes involved in RNA maturation and termination (102), although more recently, there is evidence to suggest that senataxin modulates transcription (103). Surprisingly, some mutations in the same gene can cause a juvenile form of ALS that is inherited in an autosomal dominant manner (104,105).

## 118.6 OTHER RECESSIVE PROGRESSIVE ATAXIAS

As more genetic recessive ataxias are being linked to specific loci, they are being classified as SCARs (Spinocerebellar Ataxia, Autosomal recessive). As mentioned above, Ataxia-Ocular apraxia type 2 (AO2) is also called SCAR1. In this section, we will briefly describe the other SCARs/recessive ataxias.

Spinocerebellar Ataxia, Autosomal Recessive 2 (SCAR2—MIM 213200); Cerebellar hypoplasia, nonprogressive Norman type. SCAR2 was described by (106) as an early-onset cerebellar ataxia with mental deficiency that can be associated with microcephaly, cataracts, and exaggerated tendon reflexes (106). It is not certain if SCAR2 is distinct from the disorder called cerebellar hypoplasia (MIM 213000). This disease is associated with cerebellar granule cell loss. The disease locus has been assigned to chromosome 9q34-qter (107).

Spinocerebellar Ataxia, autosomal Recessive 3 (SCAR3—MIM 271250); Spinocerebellar Ataxia with Blindness and Deafness (SCABD). This spinocerebellar ataxia was first described as an early-onset ataxia in an Israeli family. It is associated with retinal and cochlear degeneration causing blindness and deafness (108,109) and has been linked to the chromosome 6p23-p21 (110).

Spinocerebellar Ataxia, Autosomal Recessive 4 (SCAR4—MIM 607317); Spinocerebellar Ataxia with Saccadic Intrusions (SCASI). SCAR4 has been described in a family of Slovenian descent. It is a progressive ataxia with gait, trunk, and limb ataxia, associated with pyramidal signs. Most patients require walking aids by the sixth decade. This ataxia is associated with eye movement abnormalities, myoclonic jerks, fasciculations, cerebellar dysarthria, and pes cavus. There are large- and small-fiber sensory losses, and nerve condition studies show axonal sensorineural neuropathy. Neuroimaging shows cerebellar atrophy that primarily involves the dorsal vermis (111).

Spinocerebellar Ataxia, Autosomal Recessive 5 (SCAR 5—MIM 606937); Nonprogressive Congenital Cerebellar Ataxia with Mental Retardation, Optic Atrophy, and Skin Abnormalities (CAMOS). SCAR5 has been described in a large inbred Lebanese Druze family as a nonprogressive autosomal recessive ataxia that starts in early childhood and is associated with optic atrophy, mental retardation, short stature, speech defect, and cerebellar atrophy (112). This disease is associated with abnormal osmiophilic pattern of skin vessels that has been speculated to prevent normal exchange between the blood and surrounding tissues. This might also help underlie abnormalities in developmental processes involved in neurigenesis and neuronal migration. The disease locus has been mapped to a 3.6-cM interval on chromosome 15q24-q26 (113).

Spinocerebellar Ataxia, Autosomal Recessive 6 (SCAR6—MIM 608029); Norwegian Nonprogressive Infantile Cerebellar Ataxia (CLA3). SCAR6 was first described in a large inbred Norwegian family, ranged in age from 4 years to 59 years. All patients showed a nonprogressive cerebellar ataxia manifesting in early childhood associated with short stature and flat feet. The phenotype of this disorder includes defects in motor coordination, slow speech, poor eye movement coordination, slight spasticity, and normal intelligence (114). The disease has been chromosomally mapped to a 19.5-cM interval on chromosome 20q11-q13 (115).

Spinocerebellar Ataxia, Autosomal Recessive 7 (SCAR7—MIM 609270). SCAR7 has been described in a nonconsanguineous Dutch family. SCAR7 presents with slowly progressive spinocerebellar ataxia, dysarthria, nystagmus, saccadic pursuit eye movements, a postural tremor, hyperreflexia, extensor plantar responses, and decreased vibration sense (116). The disease severity is variable ranging from mild ataxia to wheelchair bound. The gene for SCAR7 has been tentatively mapped to a 5.9-cM interval on chromosome 11p15 (116).

Spinocerebellar Ataxia, Autosomal Recessive 8 (SCAR8—MIM 610743); Cerebellar ataxia, autosomal recessive, type 1 (ARCA1); Recessive ataxia of Beauce. SCAR8 was identified in 26 French Canadian families mostly from the Beauce and Bas-St-Laurent regions of the province of Quebec in Canada. This autosomal recessive disease starts at 17 to 46 years of age with a relatively pure cerebellar ataxia although patients often display mild oculomotor abnormalities, occasional exaggerated tendon reflexes in the lower extremities. Neuroimaging shows diffuse cerebellar atrophy (117).

SCAR8 has been mapped to chromosome 11p15 with various mutations in the gene *SYNE1* (118). *SYNE1* encodes a very large protein with 8797 amino acid residues. *SYNE1* is a part of the spectrin family, a group of structural proteins that share a common function of linking the plasma membrane to the actin cytoskeleton, a protein that is abundantly expressed in Purkinje cells and neuromuscular junctions (118). A splice-site

mutation was the most common mutation, occurring at a frequency of 50.8% among 124 patients (117). SCAR8 shows slow progression and causes moderate disability.

Spinocerebellar Ataxia, Autosomal Recessive 9 (SCAR9—MIM 612016); Cerebellar ataxia, autosomal recessive, type 2 (ARCA2). SCAR9 has been described in a consanguineous Algerian family and in three other sporadic patients with slowly progressive childhood-onset gait ataxia and cerebellar atrophy. SCAR9 is often associated with pes cavus, exaggerated tendon reflexes, mild psychomotor retardation, and mild axonal degeneration of the sural nerve. An unusual feature in some patients is exercise intolerance that is associated with elevated serum lactate. SCAR9 is caused by a homozygous splice-site mutation in the *aarF*-domain-containing kinase 3 gene (*ADCK3*) (chromosome 1q41). *ADCK3* is a mitochondrial protein homologous to the yeast CoQ8 and the bacterial UbiB proteins required for Muscle coenzyme Q10 (CoQ10 or ubiquinone) biosynthesis (119). Most of the SCAR9 patients showed decreased level of CoQ10 (119). Intriguingly, CoQ10 deficiency had been reported low in some patients with childhood-onset cerebellar ataxia (120). It is likely that CoQ10 supplementation will be beneficial for SCAR9 patients, as has been suggested for other mitochondrial respiratory chain dysfunction-related ataxias.

Cerebellar Ataxia, Cayman Type (*ATCAY*—MIM 601238). *ATCAY* is a recessive nonprogressive ataxia described in an isolated population from the Grand Cayman Islands. Ataxia is associated with hypotonia from birth, psychomotor retardation, nystagmus, intention tremor, and dysarthria. Neuroimaging shows isolated cerebellar atrophy. The *ATCAY* gene has been identified and maps to chromosome 19q13.3 (121,122,123). The *ATCAY* gene is expressed only in neurons in the brain and in components of the spinal cord and peripheral nervous system. Two mutations identified include nucleotide substitutions, one in exon 9 resulting in a serine to arginine substitution, and one in intron 9 that interferes with splicing (124). *ATCAY* encodes the caytaxin protein, a protein that shares a conserved domain with *TTPA* (see Vitamin E deficiency syndromes, above). However, it does not appear that caytaxin binds vitamin E, and its role is still unclear.

Infantile-Onset Spinocerebellar Ataxia (*IOSCA*—MIM 271245). *IOSCA* was first described in Finland, with a population carrier frequency of more than 1:230. It maps to 10q24 (125). As its name suggests, dysfunction starts in infancy (9–18 months of age) with muscle hypotonia, athetosis, ataxia, ophthalmoplegia, sensorineural hearing deficit, sensory axonal neuropathy, epileptic encephalopathy, and female hypogonadism (126,127). Other features include sensory axonal neuropathy and progressive atrophy of the cerebellum, brain stem, and the spinal cord (127). As children, most patients develop migraine-like headaches and seizures progressive to a severe epileptic encephalopathy (128). Some patients

have psychiatric problems including disorders of mood or even psychosis. Brain imaging and postmortem pathology show widespread brain edema and necrosis.

*IOSCA* results from a recessive mutation in *C10orf2* encoding Twinkle (Y508C), a mitochondrial deoxyribonucleic acid (mtDNA)-specific helicase (125). Different mutations in this same gene cause autosomal-dominant progressive external ophthalmoplegia (adPEO) with multiple mtDNA deletions (MIM 606075), a neuromuscular disorder sharing a spectrum of symptoms with *IOSCA* (125). The depletion of mtDNA has been shown in *IOSCA* patients' brains and places *IOSCA* in the family of mtDNA depletion syndromes (129).

One such disorder is *Autosomal Recessive Spastic Ataxia of Charlevoix-Saguenay* named after the region in Quebec, where it was first described. The gene, mapping to chromosome 13q11, has recently been cloned (130). It encodes a large protein with a predicted molecular weight of 437kDa that shares some homology to molecular chaperones, proteins speculated to play a role in protein misfolding. This is intriguing, since protein misfolding appears to be central to the polyglutamine induced autosomal dominant ataxias, as will be discussed later in this chapter.

*Wolfram syndrome* is a rare ataxia characterized by diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (*DIDMOAD*) (4p16), can also present with ataxia. It is now known to be caused by a mutation in a transmembrane protein expressed predominantly in the pancreas and the brain (131).

Among the cerebellar ataxias yet to be genetically characterized are *Marinesco-Sjögren syndrome*, wherein cerebellar ataxia coexists with congenital cataracts, impaired physical growth, mental deficiency, myopathy and skeletal abnormalities, and *Mathews-Rundle syndrome* in which ataxia is combined with hypogonadism.

## 118.7 THE AUTOSOMAL-DOMINANT HEREDITARY ATAXIAS

The autosomal-dominant cerebellar ataxias have an interesting history. They were first recognized by Marie in 1893 as a syndrome distinct from *FRDA*, based on their clinical features (132). Gordon Holmes criticized Marie for lumping together clinically and pathologically heterogeneous group of ataxias, with only some being clearly documented as familial (133). Nonetheless, we now know that there are indeed numerous adult-onset autosomal dominant ataxias. Several classifications have been proposed to sort individual members of the group by clinical spectrum. The most recent was proposed by Anita Harding in 1984. She divided these ataxias into three distinct groups called autosomal-dominant cerebellar ataxia types I, II and III: where type I syndromes are associated with ophthalmoplegia, optic atrophy, dementia, and extrapyramidal features; type II with pigmented maculopathy (with or without ophthalmoplegia or

extapyramidal features); while type III syndromes are pure ataxic syndromes.

Over the last several years, however, a new classification based on the genetic loci of the spinocerebellar ataxias (SCA) has gained wide acceptance. These loci have been numbered, based on their order of identification: SCA1 through 31 (and the number is bound to grow with advancements in positional cloning). In previous editions, we have tried to correlate the older Harding classification with this genetic nomenclature; however, because of the broad overlap of clinical features and phenotypic variations within each disorder, such a correspondence is difficult to achieve. Therefore, we now favor a purely genetic classification based on the genetic loci of the SCAs. Several of the SCAs are nucleotide repeat disorders and, therefore, present with the common findings of anticipation and increased severity correlating to the size of the nucleotide expansions within the relevant gene (134); Table 118-3.

### 118.7.1 Spinocerebellar Ataxia Type 1 (SCA1—MIM 164400)

Spinocerebellar ataxia type 1 was the first dominantly inherited ataxia gene to be linked to a locus (6p22-23). It is characterized by progressive cerebellar ataxia, dysarthria, oculomotor deficits, and relentless bulbar dysfunction including dysphagia and respiratory failure that results in death. Other accompaniments include hyperreflexia, increased tone, and extensor plantar responses. Occasionally the peripheral nervous system involvement can obscure these upper motor neuron findings and can result in wasting of the extremities and generalized fasciculations. The disease most often presents in the third decade of life, but there is tremendous variability in onset and clinical severity (as early as 4 years of age and as late as 60) (135). In fact, it was this clinical feature that led to a targeted search for trinucleotide repeat expansions, known to be the defect in causing anticipation in other neurodegenerative conditions. Pathologically, the primary sites of neurodegeneration in SCA1 include cerebellar Purkinje cells, brain stem cranial nerve nuclei, and the inferior olive and spinocerebellar tracts (135).

SCA1 is caused by a CAG repeat expansion in the coding region of a novel gene *SCA1* that was mapped to chromosome 6p22-23 and the mutation identified using a positional cloning approach (136,137). Even in the general “normal” population, the number of CAG repeats is polymorphic and ranges from 6 to 44. In patients, the CAG repeats range from 39 to 82 on SCA1 chromosomes (138,139). The distinction between disease-causing and “normal” alleles in the range of overlap is made on the basis of the fact that the repeat tract on normal chromosomes is interrupted by 1 to 4 CAT trinucleotides in alleles with 20 or more repeats, whereas SCA1 chromosomes contain a “pure,” uninterrupted CAG tract (140).

There is an inverse correlation between repeat size and age of onset. Patients with 70 or more CAG repeats have childhood-onset, a rapidly deteriorating course, and death within 4–5 years, whereas adult-onset patients have fewer than 70 repeats and typically live 10–20 years after symptoms appear (135). A prominent feature of SCA1, like other polyglutamine disorders, is *genetic anticipation* or the tendency of affected individuals in each successive generation of a kindred to show earlier and earlier disease onset (often with worsening severity). The mechanism involves progressive expansion of the polyglutamine repeats in disease alleles, in particular those that are transmitted through the father (137).

In SCA1, the protein carrying the CAG repeats is ataxin, a protein encoding 792–830 amino acids, depending on the size of the repeat (136). Ataxin-1 appears to be a nucleoplasmic shuttling protein that is predominantly nuclear in neurons and cytoplasmic in peripheral cells (138,139). A 120-residue region of the protein shares significant sequence similarity with the HMG-box transcription factor HBP1. This domain is thought to play a role in protein–protein interactions and possibly in protein–RNA interactions (104,105).

The cellular functions of ataxin-1 are still unclear. Loss of ataxin-1 function alone, however, cannot explain SCA1 pathogenesis, given that mice lacking ataxin-1 do not display ataxia or neuronal degeneration—although they do have spatial and motor learning deficiencies as well as impairment of short-term plasticity (141). On the other hand, there is considerable support for a gain-of-function pathogenic mechanism. The first evidence came from mice overexpressing a mutant *SCA1* cDNA with 82 glutamines (82Q) specifically in Purkinje cells. These mice developed progressive ataxia and Purkinje cell degeneration (142). The mutant ataxin-1 accumulates in nuclear inclusions (NIs) along with components of the proteasome, suggesting that mutant ataxin-1 might misfold and resist degradation (143). Similarly, fruit flies that overexpress human ataxin-1 (82Q) also developed progressive neuronal degeneration and ataxin-1-containing NIs that colocalized with chaperones and ubiquitin. Moreover, NIs have also been noted in other glutamine repeat diseases as well. These inclusions not only contain ataxin-1 but they also stain positive for chaperones and components of the ubiquitin-proteasomal pathway, both instrumental in protein clearance. Recent work suggests a scenario where ataxin-1 tends to accumulate in SCA1, probably because of an altered conformation induced by the polyglutamine tract. Ubiquitination and proteasomal degradation probably represents an appropriate response since interventions to prevent these processes in SCA1 and other polyglutamine diseases only serve to increase neuronal toxicity (144–147). Based on these findings, strategies aimed at improving protein folding or clearance are gaining center stage (148).

To characterize the effects of the SCA1 mutation on all ataxin-1-expressing neurons, an expanded CAG tract of

<sup>a</sup>34–100 can be premutations (see text).

<sup>b</sup>Alleles with 21 or more repeats are interrupted by 1–3 (CAT) units; disease alleles contain pure CAG tracts.

154 repeats was targeted in place of the typical 2 CAGs present in the endogenous mouse locus. *Sca1*<sup>154Q/+</sup> mice reproduced several key features of human SCA1 including ataxia, brain stem dysfunction, Purkinje cell degeneration, and premature death (149).

Several insights into SCA1 pathogenesis have come from studying the cellular properties of ataxin-1. For instance, phosphorylation of ataxin-1 at serine 776 (S776) appears to be important for ataxin-1 accumulation.

Moreover, mice that express ataxin-1 (82Q) that cannot be phosphorylated at this site (with an alanine at position 776) do not develop ataxia or pathology in spite of the long glutamine tract. These data show the following: (1) toxicity is mediated by the protein and not RNA; (2) the protein context is very important given that a single amino acid change abrogated accumulation and toxicity; and (3) a long polyglutamine tract can be efficiently handled by the cell's degradation machinery (150).

Furthermore, there is evidence to suggest that toxicity of ataxin-1 depends on its native but not novel, protein interactions (151). Lim et al. proposed a two-pronged model of SCA1 neurodegeneration in which increased function of a particular stable endogenous protein complex is combined with a simultaneous loss of function of other, stable endogenous protein complexes (152). Although the precise functions of ATXN1 remain elusive, several findings implicate ATXN1 in gene regulation by interacting with chromatin-modulating proteins and transcription factors (153–159).

No treatment is currently available for SCA1. Patients experience progressive limitations in their activities, lose the ability to walk, and eventually become bedridden. So far, based on studies in SCA1 animal models, it appears that lithium and neural stem cell transplantation in the cerebellum could be viable therapeutic approaches for SCA1 patients (160,161).

SCA2 (SCA2-MIM18309) was described as a form of dominantly inherited spinocerebellar ataxia that occurs at an estimated frequency of 41 per 100,000 in the province of Holguine, Cuba (162). It has since been described in several regions of the world (163). SCA2 is characterized by ataxia, dysarthria, tremor, and extremely slow saccades. Hyporeflexia of the upper limbs and ophthalmoparesis are seen in over half the patients. Dementia occurs in a significant minority of patients. Genetically, it was set apart from SCA1 when its locus (12q23-24) was identified (164–166).

Age of onset varies (2–65 years); when SCA2 alleles contain more than 200 repeats, the disease can present as early as infancy with hypotonia, developmental delay, dysphagia, and retinitis pigmentosa (167). The genetic background may be relevant, since atypical features are seen in geographically distinct families: mental deterioration in an Italian family (167,168), for example, and chorea and dystonia in families from Tunis and Martinique (169,170). At a pathological level, there is severe loss of Purkinje cells and of neurons in the substantia nigra and basis pontis. Mild to moderate neuronal loss is also seen in the inferior and accessory olives; dentate, arcuate, gracile, and accessory cuneate nuclei; internal granule cell layer of the cerebellum; and in the anterior horns of the spinal cord. Axonal loss from the dorsal roots and posterior columns, the dorsal spinocerebellar tract, and often from the anterior spinal roots is also found. Reactive gliosis can be seen in the globus pallidus, thalamus, subthalamus, and periaqueductal regions (171,172).

The CAG trinucleotide repeat lies within the coding region of a novel protein termed ataxin-2 that was identified by positional cloning (173–175). Normal alleles vary between 15 to 24 CAG repeats (with 22 repeats found 94% of the time), while disease alleles have 35 to 59 repeats. The range of pathogenic alleles in SCA2 is shifted toward shorter repeats compared with other SCAs, suggesting that the expanded repeat within

ataxin-2 is more deleterious to neurons. The CAG repeat in the SCA2 gene is interrupted by 1 to 3 CAA units only on normal alleles suggesting that, as in SCA1, interruption of CAG repeats confers stability. Finally, there is a strong inverse correlation between the size of the repeat and the age of symptom onset.

The SCA2 gene contains 25 exons and two alternately spliced forms of mRNAs are generated, one of which results in a protein that is truncated by 70 amino acids (176). Ataxin-2 mRNA is found in multiple tissues and in all regions of the CNS (173–175) where it is present predominantly in neurons and is highly expressed in Purkinje cells (171).

The SCA2 gene encodes a protein called ataxin-2 that contains structural elements that appear to be important in RNA splicing. Ataxin-2 regulates the intracellular concentration of its interaction partner, the poly(A)-binding protein, a stress granule component and a key factor for translational control (177). Ataxin-2 is associated with rough ER (178). Ataxin-2 associates with polyribosomes under normal conditions and is recruited to stress granules upon environmental stress. Mutant ataxin-2 sensitizes Purkinje cells to glutamate-induced apoptosis. Glutamate-induced cell death of 58Q PC cultures was attenuated by dantrolene, a clinically relevant ryanodine receptor (an intracellular calcium channel) inhibitor and Ca<sup>2+</sup> stabilizer. Thus, neuronal Ca<sup>2+</sup> signaling may play an important role in SCA2 pathology, and the ryanodine receptor could be a potential therapeutic target for treatment of SCA2 patients (179). Intriguingly, a recent study implicates this gene as a modifier of amyotrophic lateral sclerosis (180).

SCA3 or Machado-Joseph disease (MJD; MIM 109150) is probably the most common of the autosomal dominant spinocerebellar ataxias and also has a broad clinical spectrum. In fact, the disease initially linked to the spinocerebellar ataxia 3 locus was not recognized as an MJD variant, since the initial SCA3 patients did not exhibit the extrapyramidal syndrome which was then thought to be characteristic of the MJD syndrome. Only when linkage analysis assigned both of these ataxic syndromes to the same genetic locus on the long arm of chromosome 14 (14q24.3-q32) did it become clear that they were one and the same polyglutamine disease (181). SCA3 encodes a protein referred to as ataxin-3, a 42 kDa predominantly cytoplasmic protein. MJD is also a CAG repeat disorder. Normal MJD1 alleles contain from 13 up to 47 CAG repeats, while expanded alleles contain 45–84 repeats (182). Much like SCA1, the mutant protein forms nuclear inclusions (183,184).

Besides ataxia, clinical features in SCA3 include slow saccades and saccadic pursuit. Other features include lid retraction that gives the impression of a persistent stare, and signs of brain stem dysfunction including dysarthria, difficulty in swallowing, poor cough, and tongue fasciculations. Cognitive impairments such as deficits in verbal

and visual memory, poor verbal fluency, and visuospatial impairments and autonomic dysfunction have also been described (185,186). Because of peripheral nervous system involvement, the neurological examination usually shows a mix of upper motor neuron and lower motor neuron findings. Thus tone can range from hypotonia to significant rigidity, and reflexes can be exaggerated or absent. The plantar response tends to be extensor. The common extrapyramidal features include rigidity and dystonia. In the past, MJD had been subclassified as type I when spasticity was the major sign without significant ataxia; type II when ataxia was alone; and type III when ataxia was accompanied by peripheral neuropathy. Beyond formalizing the phenotypic variability that we now know is most likely contributed by genetic background and polyglutamine length, this classification adds little to the diagnosis.

Ataxin-3 is the smallest of the polyglutamine proteins with a ubiquitin interaction motif (UIM) situated near the polyglutamine domain. Several isoforms have been described. Ataxin-3 interacts with Rad23 and valosin-containing protein (VCP) (187). Rad23, a member of proteasomal protein degradation machinery, in turn, interacts with the proteasome subunit S5a, suggesting a role of the protein complex in “protein shuttling” for translocating proteins to the proteasome for degradation. VCP, also called CDC48, is an ATPase associated with various activities and has been implicated in multiple cellular functions ranging from organelle biogenesis to ubiquitin-dependent protein degradation (reviewed in Reference (182)). Mutation in VCP causes inclusion body myopathy with Paget disease and frontotemporal dementia (IBMPFD MIM 167320). Interestingly, Parkin, the E3 ubiquitin ligase, which is frequently mutated in early-onset autosomal recessive Parkinson’s disease, promotes ubiquitination and degradation of ataxin-3 (188).

The pathogenesis of MJD/SCA3 is still poorly understood. The introduction of ataxin-3 with an expanded polyglutamine tract into cultured cells induces apoptosis, suggesting that the mutant protein is either directly or indirectly involved with a cellular suicide pathway (183). Other studies suggest that protein misfolding, presumably initiated by the expanded polyglutamine tract, leads to ubiquitination and subsequent formation of intranuclear inclusions (144,145). This is a common pathway in polyglutamine expansion diseases. How this leads to cell dysfunction and death and why the clinical timecourse takes so long to evolve remain unknown.

SCA4 (MIM 600223) has no unique features that distinguish it from the other ataxias, except perhaps for an exaggerated sensory axonal neuropathy and extensor plantar reflexes (189,190). The gene, which maps to 16q22.1, has yet to be identified.

SCA5 (MIM 600224) and 6 (SCA6—MIM 183086) are both characterized by an almost pure cerebellar

syndrome with global cerebellar atrophy. SCA5, in particular, is a relatively mild syndrome with a slow progression. The disease is caused by mutations in the beta III spectrin gene (SPTBN2) (191) located on the centromeric region of chromosome 11 (192). As an interesting historical aside, SCA5 was described initially in descendants of President Abraham Lincoln’s family.

SCA6 is more common than SCA5. Indeed in some studies it accounts for 15–17% of dominant cerebellar ataxic syndromes (193–195), and see review in Reference (196). The mutation is occasionally found in sporadic cases as well. In SCA6, there is occasional horizontal and vertical nystagmus and abnormal vestibulo-ocular reflex (197). Both diseases begin in the third decade, and MRI examinations on affected patients show cerebellar atrophy. SCA6 is known to be a polyglutamine disorder (198). The CAG tract, however, is small compared with that of other polyglutamine diseases—21 to 33 repeats in the disease state (normal less than 18). The genetic locus was mapped to chromosome 19q13, where a CAG repeat expansion in exon 47 at the 3’ region of the *CACNA1A* gene was identified as the causative mutation (198). *CACNA1A* codes for the brain-specific, voltage-sensitive  $\alpha_{1A}$  ( $Ca_v2.1$ ) subunit of the P/Q-type calcium channel, which is highly expressed in Purkinje cells (199). Alternative splicing leads to six isoforms, three of which contain the polyglutamine sequence. Repeat expansions are the smallest of the triplet repeat diseases, with 21 or more repeats being pathogenic. Individuals who are homozygous for expanded repeats show no phenotypic or age of onset differences (200). Phenotypic severity is inversely correlated with the number of CAG repeats, as is the age of onset (201). Clinical anticipation has been observed, but does not always appear to stem from CAG repeat instability. No CAA interruptions are present in the repeats. Proteins with the expanded repeat aggregate specifically in the cytoplasm of Purkinje cells (199). These cytoplasmic inclusions are not ubiquitinated and lack several other components found in the inclusions of other CAG repeat disorders.

Possible mechanisms of neuronal cell degeneration include increased calcium channel entry and cytoplasmic aggregation of channel protein (199,202). Intriguingly, this gene has been implicated in episodic ataxia type 2 and familial hemiplegic migraine, although the mutational mechanisms are distinct (203). Nonetheless, compromise of the function of the calcium channel might be central to all three, since there is some overlap of symptoms. Like episodic ataxia, SCA6 can present with intermittent ataxia in the early stages, and all three conditions (SCA6, EA2, and familial hemiplegic migraine) often involve cerebellar atrophy. Nakamura et al. in a 4-week trial on 11 SCA6 patients showed that treatment with Gabapentin, which interacts with  $\alpha_{2\delta}$  subunit of the P/Q-type Voltage-dependent calcium channel, might be beneficial for SCA6 patients (204).

Pathology specimens demonstrate loss of Purkinje and granule cells, with proliferation of Bergmann glia, that is more prominent in the vermis than in the hemispheres (197,201). Loss of inferior olive neurons also occurs, but may be secondary to the cerebellar changes.

Families with significant phenotypic overlap have been identified, leading some to postulate that the three disorders represent a spectrum of disease rather than truly separate entities. The identification of small triplet expansions (20 and 23 repeats) in two kindreds whose members presented with EA2, and the identification of a point mutation leading to early hemiplegic migraine, and later progressive ataxia, is supportive of this interpretation (205,206).

Among the spinocerebellar ataxias, SCA7 (SCA7—MIM 164500) has perhaps the most variable expression. When the onset is in childhood, seizures and myoclonus along with cardiac involvement are seen alongside the usual features of ataxia. (207,208). It can be rapidly debilitating, culminating in death by age three or earlier. The infantile-onset form is also associated with cardiac abnormalities, particularly patent ductus arteriosus (207,209,210). Childhood-onset SCA7 is less aggressive than the infantile-onset form but more progressive than the adult-onset form.

In adults, ataxia is accompanied by oculomotor abnormalities. Other features include pyramidal tract signs, supranuclear ophthalmoplegia, and dysarthria/dysphagia; occasionally dementia and deafness are seen as well (207). In both childhood and adult cases, visual loss from pigmentary macular degeneration is almost invariable and can precede the ataxic syndrome. Since this sets it apart from the other autosomal dominant ataxias, defects in color vision and electroretinogram abnormalities might suggest the diagnosis in early cases (211) (reviewed in Reference (212)). The retinal changes in SCA7 start in a central location and move peripherally as the disease progresses, thus distinguishing the eye findings from those in retinitis pigmentosa.

Brain imaging in all cases typically demonstrates cerebellar atrophy; ventricular dilatation and delayed myelination can be found in infantile cases. Brain pathological specimens show atrophy of the cerebellum with loss of dentate neurons and Purkinje cells, and loss of inferior olivary neurons in the brain stem; posterior column, dorsal and ventral spinocerebellar tract loss in the spinal cord; and macular degeneration with loss of photoreceptive cells in the retina.

SCA7 is a glutamine repeat disorder mapping to chromosome 3p12-p21.1 (211,213,214). SCA7 accounts for roughly 5 percent of dominant spinocerebellar ataxias (193,195). SCA7 encodes a novel protein, ataxin-7, with a polyglutamine tract at the amino-terminus (215). The SCA7 CAG repeat ranges in size from 4 to 35 repeats in normal alleles, and from 37 to 306 repeats in expanded alleles. Another notable feature of SCA7 is the

remarkable intergenerational instability, with expansion particularly likely upon paternal transmission (215,216). An inverse correlation exists between repeat length and age of onset, and repeat expansions >59 repeats tend to develop visual impairment prior to ataxia (209). Alleles ranging in size from 34 to 36 repeats have been observed in individuals who are at risk but asymptomatic at the time of evaluation (207,209,214,215).

Like SCA2, it is the extreme expansion in SCA7 that contributes to the severe infantile phenotype (207). Mice expressing mutant ataxin-7 have features similar to those seen in the human disease with neurodegeneration affecting the cerebellum and retina (217,218).

Expression of the expanded ataxin-7 protein in transgenic mice leads to the development of intranuclear inclusions and the degeneration of rod photoreceptors and Purkinje cells, findings that are consistent with the human phenotype (219). In retinal photoreceptor cells, the expression of expanded ataxin-7 is associated with alterations in gene expression that predate photoreceptor degeneration (217,220). Another interesting finding is that the speed of ataxin-7 accumulation varies in different neuronal populations, suggesting that intrinsic differences in the ability to clear mutant protein may explain the variable susceptibility of different cell types in this and other polyglutamine diseases (217). Cellular dysfunction predates the appearance of neuronal inclusions, suggesting that, while they are part of the pathogenesis, inclusions in and of themselves are not the primary cause of dysfunction (217).

Recently ataxin-7 has been shown to be a core component of a transcription coactivator complex called STAGA (reviewed in Reference (221)), the mammalian equivalent of a yeast transcription coactivator named SAGA. This complex contains histone acetyltransferase (HAT) activity, mediated by the Gcn5 enzyme. Sgf73, the yeast homologue of ataxin-7, is a component of the SAGA complex with essential function in yeast (222). Two independent groups have shown that ataxin-7 is indeed a core component of STAGA complex in mammals (223,224). It is still unclear why, in spite of ubiquitous expression of the STAGA complex, neurodegeneration happens only in specific group of neurons. The answer might underlie identification of STAGA-dependent transcription factors whose functional impairment underlies the production of the SCA7 phenotype.

SCA8 (SCA8—MIM 608768) is difficult to distinguish clinically from the other SCAs. Pathologically, there appears to be degeneration of Purkinje, inferior olivary, and nigral cells, accompanied by periaqueductal stenosis, with MRI of the brain demonstrating cerebellar atrophy (225) (SCA8 was mapped to chromosome 13q21, and the vast majority of disease alleles in individuals of European descent share a common haplotype (226).

Genetically, SCA8 is the only SCA with a possibly novel mechanism of pathogenesis for triplet repeat disorders that involves a CTG expansion in the noncoding

region of the relevant gene. There is a high variability in the repeat length of wild-type alleles: more than 99% of unaffected individuals have repeat lengths less than 74, but a few unaffected individuals have 800 repeats, by far the largest number of normal repeats of any SCA. This remarkable overlap of repeat size in pathogenic and nonpathogenic alleles is unique among the SCAs. Furthermore, homozygosity for an expanded allele does not appear to exacerbate the disease phenotype, as it does in SCA1 and DRPLA. The CTG expansion shows significant genetic instability. Repeat lengths contract with paternal transmission and expand with maternal transmission, another unusual finding of this disease (227,228).

Initial studies suggested that the SCA8 gene might encode an antisense RNA that regulates the levels of a neighboring messenger RNA that encodes a putative actin-binding protein (229). More recent data suggest that the CTG expansion is transcribed in both the forward and reverse directions to yield an RNA with a CUG expansion and a peptide with CAGs encoding polyglutamines (230). It is possible that both the RNA and the protein product produce toxic effects. The RNA gain of function might be similar to that suggested for myotonic dystrophy types 1 and 2 (DM1: MIM 160900; DM2: MIM 602668)—repeat disorders where the repeat does not occur in the protein coding region of the gene. Recently, Daughters et al. have presented some evidence that SCA8 CUG<sup>exp</sup> transcripts form hallmark ribonuclear inclusions that colocalize with MBNL1 in humans and mice and that genetic loss of Mbnl1 enhances motor coordination deficits in SCA8 BAC-EXP mice. Furthermore, ATXN8OS CUG<sup>exp</sup> transcripts dysregulate MBNL1-CUGBP1 pathways in the CNS and trigger downstream molecular changes in GABA-A transporter 4 (*Gabt4*) regulation through an RNA gain-of-function mechanism (231). Unlike DMPK and ZNF9 (the genes responsible for DM1 and DM2, respectively), which have broad expression patterns, SCA8 is almost exclusively expressed in the CNS; the spatial and temporal expression differences between SCA8, DMPK, and ZNF9 could explain the phenotypic differences between these three diseases (reviewed in Reference (232)).

Thus, SCA8 appears to be a very complicated syndrome with many questions unanswered. Further confusing the picture is the coexistence of SCA8 expansions with those of SCA1, SCA3, or SCA6 in some kindreds (233,234). SCA8 expansions have also been found in patients with Alzheimer's disease, Parkinson's disease, and an individual with vitamin E deficiency heterozygous for the TTPA mutation (233,235,236). How these factors influence the pathogenesis of the disease is unknown. Although a relationship between repeat size and clinical signs was demonstrated in the initial report, other families with this disorder have shown greater variability in penetrance (226). This has led some authors in the past to question the pathogenesis of the expansion itself (237–239). It appears that sequence interruptions

of the CTG expansion and the size of the CTA tract that precedes the CTG expansion are among the multiple factors that may influence SCA8 disease penetrance.

SCA9 has not been assigned to a clinical disorder. In SCA10 (MIM 603516) seizures coexist with spinocerebellar ataxia. Mood disorders and polyneuropathy diagnosed by nerve conduction studies can also be seen, and neuroimaging shows cerebellar atrophy. SCA10 was identified in a single four-generation Mexican kindred (239) and is the second most common form of dominantly-inherited ataxia after SCA2 in people of Mexican descent and MJD in southern Brazil. This observation, along with the rarity of expanded alleles in other populations, has led to the hypothesis that the mutation arose in the New World (240). SCA10 is caused by a pentanucleotide (ATTCT) expansion in an intron of the affected gene (chromosome 22q13). Like trinucleotide expansions, pentanucleotide expansions are also unstable when transmitted paternally, leading to the clinical phenomenon of anticipation in this syndrome as well (241,242) (maternal transmission results in more stable repeats). Instability of the repeat region can lead to as many as 4500 repeats (242).

The ataxin-10 protein is widely expressed throughout the brain and in several other tissues (243). It is localized to the cytosol and perinuclear region in neurons. Whether the disease phenotype stems from genomic disruption, RNA gain-of-function, or ataxin-10 loss of function is unknown; however, decreased ataxin-10 RNA levels in primary cerebellar and cortical neuronal culture result in increased apoptosis—suggesting that loss of function may be the pathogenetic mechanism (243).

The remaining SCAs are rare. SCA11 (SCA11—MIM 604432) is a relatively mild, pure cerebellar ataxia with brisk reflexes. Mean age of onset was about 25 years. Genetic anticipation does not appear to be present. It is caused by mutations in the *TTBK2* gene that encode tau tubulin kinase-2 (locus at 15q14-q21.3) (244,245). Neuropathological examination does not reveal neuronal inclusions using hematoxylin and eosin, p62, ubiquitin or 1C2 immunohistochemistry, but neurofibrillary tangles, neuropil threads and tau-positive neuritis are visible in the medullary tegmentum, nigra, midbrain tegmentum and tectum, and putamen. The cerebellum showed cell loss but surprisingly no other visible pathology, perhaps due to the high resistance of the cerebellum to forming tangles (244).

SCA12 (SCA12—MIM 604326) is a trinucleotide repeat disorder caused by a CAG trinucleotide expansion in the 5' UTR of a gene encoding a brain-specific regulatory subunit of protein phosphatase 2A (genetic locus 5q31-q33) (246). This ataxia is often complicated by tremor, parkinsonian features, and dementia in the later stages of disease progression. In fact, action tremor is the most distinguishing clinical feature and is typically the initial symptom. Other features include hyperreflexia and abnormal eye movements. Two patients in the initial

kindred were reported with childhood-onset symptoms: one had nystagmus from birth, while the other had lower extremity dystonia that developed in childhood (247). MRI of the brain reveals both cortical and cerebellar atrophy. Pathology is available only on a single brain and revealed diffuse atrophy of cerebral and cerebellar cortices and specifically loss of Purkinje cells. SCA12 is rare except in India, where it is the third most common SCA (248,249).

Genetic analysis revealed a triplet CAG expansion on chromosome 5q31-q33. No apparent relationship exists between repeat size and age of onset. Unlike other SCAs with CAG expansions, the expanded allele does not lead to a polyglutamine tract. Rather, the CAG expansion is found in 133 nucleotides upstream of the transcription start site for PPP2R2B. The SCA12 gene product is a brain-specific regulatory subunit of protein phosphatase 2A and regulates neuronal survival through the mitochondrial fission/fusion balance (250).

SCA13 (SCA13—MIM 605259) is characterized by cerebellar ataxia and mental retardation described in French and Filipino pedigrees (251,252). It is caused by mutations in the potassium channel gene *KCN3* on chromosome 19q13 (253). Two distinct mutations have been identified in distinct Filipino and French pedigrees. Both mutations alter *KCN3* function in a *Xenopus laevis* oocyte expression system. An F448L mutation is expected to be more severe because it alters key gating properties of *KCN3* channels. In contrast, an R420H would be expected to reduce channel activity without changing the functional properties of the residual current (253). This speculation is consistent with the childhood-onset with concurrent mental retardation (IQ = 62–76) and seizures in members of the French pedigree and their absence in the Filipino patients. These mutations are expected to change the output characteristics of fast-spiking cerebellar neurons, where *KCN3* channels confer capacity for high-frequency repetitive firing.

SCA14 (SCA14—MIM 605361) is caused by missense mutations in exon 4 of the protein kinase C gamma gene, a member of a serine/threonine kinase family that is involved in cell proliferation and signal transduction processes (254–256). This gene maps to 19q13.4 (255,257,258).

The phenotype of SCA14 is quite variable. Patients who present before 27 years of age manifest axial myoclonus prior to the development of ataxia, while those with onset after age 39 present with a pure cerebellar ataxia. Gait ataxia, dysarthria, horizontal gaze nystagmus, abnormal smooth pursuit movements, hyper- and hyporeflexia, and peripheral neuropathy were described in all of the families (255,257,258). Imaging reveals atrophy of the cerebellar vermis either alone or in conjunction with the cerebellar hemispheres. Lifespan is not significantly affected, and ataxia displays a slowly progressive course. Genetic anticipation occurs. Limited pathologic specimens suggest a primary Purkinje cell defect (257).

SCA15 (MIM 606658) is a slowly progressive cerebellar ataxia that may be associated with a mild postural or action tremor and titubation. Its onset is variable from childhood to middle age (259–261). Neuroimaging typically reveals atrophy of the cerebellum, particularly the vermis. The locus for SCA15 was first mapped to 3p24.2-3pter in an Australian family (262). Hara et al. mapped two Japanese families presenting with ataxia and postural tremor of the head, arm, or trunk (263). The first family had partial deletions involving both the type 1 inositol 1,4,5-triphosphate receptor (*ITPR1*) and sulfatase modifying factor 1 (*SUMF1*) genes, and the second family had only a point mutation in *ITPR1* (P1059L). The proline was highly conserved, and the mutation was absent in 234 chromosomes in Japanese controls (263). These results suggest that *ITPR1* but not *SUMF1* is the causative gene for SCA15. On the other hand, Iwaki et al. showed that haploinsufficiency in *ITPR1* alone is the cause of what had been thought to be a different disease, SCA16 (MIM 606364) (264). Since these discoveries, SCA16 is thought to be same disorder as SCA15.

SCA17 (MIM 607136) is yet another polyglutamine disease with the expansion occurring in the general transcription factor TATA-binding protein (*TBP*) on chromosome 6q27 (265). The ataxic syndrome is associated with dementia, extrapyramidal features, and even psychiatric symptoms such as depression and hallucinations (265,266). SCA17 can also mirror Huntington disease by causing generalized chorea (267). Marked anticipation can occur as observed in Italian kindred, with the youngest family member in the fourth generation presenting with dysarthria and ataxia at age three (268). Repeat sizes of 42–48-repeats show variable penetrance. Like other expansion diseases, an inverse correlation exists between repeat size and age of onset.

Neuroimaging typically demonstrates cortical and cerebellar atrophy. SCA17 mouse models have been generated by expressing *TBP* under the prion promoter that also demonstrate a neurodegenerative syndrome. There is evidence to suggest that the expansion of the polyglutamine protein enhances the interaction of *TBP* with the general transcription factor *IIB* causing transcriptional misregulation (269). Pathologic specimens reveal neuronal loss in many brain areas, including loss of Purkinje cells (265,270). Immunostaining for ubiquitin, *TBP*, and polyglutamine tracts demonstrates their presence in intranuclear inclusions in several neuronal cell types, including Purkinje cells (265,270).

SCA18 (Sensory/Motor Neuropathy with Ataxia—MIM 607458) is an ataxic syndrome associated with pyramidal tract signs, muscle weakness, sensory axonal neuropathy, and mild cerebellar atrophy. Distal muscle weakness and atrophy along with pes cavus are occasionally seen. It has been described in an American family of Irish ancestry (257). Haplotype analysis links SCA18 to 7q22-q32. Neuroimaging may show

evidence of mild cerebellar atrophy. EMG/NCV shows evidence of denervation and axonal sensory neuropathy. Thus, the overall picture is one of a mixed cerebellar degeneration and peripheral neuropathy. There is evidence to suggest that the interferon-related developmental regulator gene 1 (IFRD1) is mutated in this disease (271).

SCA19 (MIM 607346) was identified in a single Dutch family and manifests as a relatively mild cerebellar ataxia with cognitive impairment, myoclonus, and tremor. Imaging shows atrophy of the cerebellar hemispheres or vermis (272). SCA19 links to chromosome 1p21-q21 (273), a region that has also been linked to SCA22. Thus, SCA19 and SCA22 are probably allelic forms of the same gene ((274) #4503).

SCA20 (MIM 608687) is an ataxic syndrome described in a family of Anglo-Celtic descent that maps to chromosome 11 (275). Age of onset in 14 family members was 19–64 years (mean 46.5). In this disease, dysarthria is usually the presenting feature with subsequent limb ataxia, palatal tremor, and dysphonia. This disease is also characterized by calcification of the dentate nucleus visualized by brain imaging with CT or MRI. The genetic locus overlaps with that of SCA5, so the separate identity of this SCA remains to be established.

SCA21 was identified in a French family as gait ataxia and akinesia, with variable features of dysarthria, hyporeflexia, and mild cognitive impairment. Brain imaging shows marked atrophy of the cerebellum. Eye movements are typically preserved, and disease progression is slow. The phenomenon of anticipation has been suggested; however, the responsible gene has not yet been identified. SCA21 maps to chromosome 7p21.3-p15.1 (276,277).

SCA22 was identified in a Taiwanese family mapping to chromosome 1p21-q23 (278). Clinically, this is a slowly progressive ataxia with variable dysarthria and hyporeflexia, with neuroimaging showing cerebellar degeneration (46). As mentioned earlier, it is likely that SCA19 and SCA22 are allelic forms of the same gene (272,274,279).

SCA23 is a late-onset (age > 40 years) ataxia described in a Dutch family mapped to chromosome region 20p13-p12.3. 2 (280). It is associated with variable dysarthria, ocular dysmetria, and distal sensory deficits (280). Neuroimaging demonstrates severe cerebellar atrophy. Pathological examination in a single patient who died at 80 years of age showed loss of Purkinje cells, neurons in the dentate nuclei and inferior olives and thinning of the cerebellopontine tracts. Also observed was demyelination of the posterior and lateral columns in the spinal cord—and ubiquitin-positive, polyglutamine-negative intranuclear inclusions in nigral neurons that resembled Marinesco bodies.

SCA24, unlike the other SCAs that are autosomal dominant, is a recessively inherited ataxia. It has therefore been redesignated as SCAR4 (see below).

SCA25 (MIM 608703) was described in a French family as a cerebellar ataxia with sensory neuropathy (281). The phenotype itself is variable with regard to age of onset, severity, and clinical manifestations. Thus, the disease can range from infantile-onset cerebellar ataxia with pure sensory neuropathy, suggestive of Friedreich's ataxia, to a form with mild cerebellar ataxia and prominent sensory neuropathy suggestive of Charcot-Marie-Tooth SCA25 maps to chromosome 2.

SCA26 (MIM 609306) was described in a Norwegian family. It is characterized by a pure slowly progressive cerebellar ataxia with autosomal dominant inheritance (282). SCA26 maps to chromosome 19p13.3 that is located close to the locus responsible for SCA6 (282). Genetic analysis, however, has excluded mutations in CACNA1A gene (the gene mutated in SCA6).

SCA28 (MIM 610246) was first described in an Italian family. It is characterized by a juvenile-onset (mean age 19.5 years), slowly progressive cerebellar ataxia with eye movement abnormalities and, in some cases, pyramidal tract signs. Associated features include dysarthria and hyperreflexia (283,284). SCA28 is caused by missense mutations in the mitochondrial protease gene AFG3L2, a gene that maps to chromosome region 18p11.22-q11.2 (285). AFG3L2 protein is a homolog of paraplegin, a protein mutated in one form of hereditary spastic paraplegia (SPG7). AFG3L2 and paraplegin are nuclear-encoded mitochondrial proteins that form a hetero-oligomer. Both of these proteins belong to the family of m-AAA proteases that are involved in protein quality control in the inner mitochondrial membrane. Mutations in paraplegin are responsible for a recessive form of hereditary spastic paraplegia (SPG7—MIM 607259), whereas mutant forms of AFG3L2 cause dominantly inherited SCA28. Haploinsufficient mice for AFG3L2 recapitulate important pathophysiological features of the human disease. Respiratory chain dysfunction and increased production of the reactive oxygen species might explain the pathophysiology of SCA28 (286).

SCA29 (MIM 117360) is characterized by an early-onset, and nonprogressive ataxia is characterized by a variable atrophy of the cerebellar vermis. It maps to chromosome 3p26 and may be an allelic variant of SCA15 described above (287).

SCA30 is an ataxia with a mid- to late-life onset associated with hypermetric saccades and minor pyramidal signs described in an Australian family of Anglo-Celtic origin (288). Brain MRI shows atrophy of the cerebellar vermis and cerebellar hemisphere. SCA30 maps to chromosome 4q34.3-q35.1. The patients did not have nystagmus or neuropathy.

SCA31 (MIM 117210) is characterized by late-onset cerebellar ataxia and reduced muscle tone that may be associated with sensorineural hearing loss (289–291). Notably, there are no signs of pyramidal tract involvement

(190). It maps to chromosome 16q22.1, close to SCA4. SCA31 is caused by an insertion containing pentanucleotide repeats including a long (TGGAA)<sub>n</sub> sequence within introns of the TK2 gene and the BEAN gene (on opposite strands and transcribed in opposite directions) (292).

Based on this summary of the known autosomal dominant spinocerebellar diseases and their phenotypes, it should not be misconstrued that all genes contributing to dominant spinocerebellar ataxia have been identified. Indeed, only 60–70% of patients have mutations in the known loci. This situation is likely to change and web-based resources such as the Online Mendelian Inheritance of Man ([www.OMIM.org](http://www.OMIM.org)) provide an excellent means for keeping track of advances in this area.

Besides the numbered spinocerebellar ataxias, other autosomal dominant conditions that result in ataxias include dentatorubropallidoluysian atrophy (DRPLA). This ataxia is relatively common in Japan. It should be suspected when ataxia and rigidity are accompanied by choreoathetosis, myoclonic epilepsy, and dementia. Other features include hyperreflexia and slowing of saccades. Caused by an expanded CAG repeat, DRPLA presents with anticipation, especially when transmission is via the father. The relevant protein encoded by the *DRPLA* gene (locus 12p) is called atrophin-1. This is a cytoplasmic protein with a molecular weight of 125 kDa (293,294). Calcification of the basal ganglia and leukodystrophic changes are often seen on imaging studies. Haw–River syndrome is a variant of DRPLA, without the characteristic myoclonic epilepsy, seen in a few families of African American descent in North Carolina.

Another ataxia that should be mentioned in the differential of spinocerebellar ataxic conditions is the Fragile X-associated tremor ataxia syndrome (FXTAS). This disease is seen in some older men (approximately a third) who carry a permutation in the fragile X mental retardation 1 gene (*FMR1*) (a gene on the X chromosome) (295–297). Fragile X syndrome, a common cause of mental retardation in males, is caused when the CGG expansion extends typically beyond 200 and is not associated with ataxia or tremor. The premutation consists of a trinucleotide CGG repeat length ranging from 50 to 200. It is also associated with dementia, parkinsonism, and autonomic dysfunction. Since the prevalence of the premutation carrier state is as high as 1 in 813 males, this syndrome could prove to be a common genetic cause of ataxia. Increased age and length of the CGG expansion are associated with worsening neurological features. FXTAS was thought to only affect men carrying the permutation. Women have been identified with this syndrome likely because of X inactivation of the normal allele. Premutation carriers in women can present with premature ovarian failure. The molecular mechanism causing FXTAS differs from that causing the fragile X syndrome. In fragile X syndrome, methylation of DNA sequences in the promoter where the

expanded CGG resides causes silencing of the *FMR1* gene and complete loss of *FMR1* protein. In FXTAS, fragile X RNA is produced but it is poorly translated into protein. This translational deficit is thought to cause a compensatory increase in the levels of *FMR1* transcripts. Unfortunately, the RNA bearing the expansion now causes a toxic gain-of-function effect triggering a downstream protein accumulation and neurodegeneration (298). Experimental mouse and *Drosophila* models have highlighted the similarity between FXTA and polyglutamine induced ataxias (299,300). This is an active area of research, with implications for some of the other repeat disorders in untranslated regions of RNA, including SCAs 8, 10 and 12.

Another class of diseases that may resemble the spinocerebellar ataxias are the prion disorders with mutations in the prion or *PRNP* gene. Of these, *Gerstmann–Straussler–Scheinker disease* (GSS), particularly the ataxic variant, is the most likely to mimic a spinocerebellar syndrome. GSS is diagnosed when autosomally dominant ataxia coexists with cognitive and motor decline alongside pathological findings of prion protein-containing amyloid plaques. Unlike those afflicted with the other SCAs, GSS patients often complain of altered sensation or even occasional leg pain; moreover, they go on to rather rapidly develop cognitive decline and EEG changes, similar to the more common variants of prion diseases such as CJD. GSS represents a group of at least six mutations in the *PRNP* gene, with the ataxic variant caused by a proline to leucine missense at codon 102 (301–303).

### 118.7.2 Diagnostic Studies in the Autosomal Dominant Spinocerebellar Ataxias

In all autosomal dominant ataxias, neuroimaging studies by Magnetic Resonance Imaging (MRI) and Computerized Axial Tomography (CAT) mirror the clinical and pathological phenotypes of each of the spinocerebellar ataxias. Cerebellar atrophy is the most commonly reported finding, along with enlargement of the fourth ventricle. The relative amounts of degeneration vary, with SCA2 patients showing the most atrophy and those with SCA5 and 6 the least. Surprisingly, brain stem atrophy, which one would expect to be almost universal, can be minimal in SCA3 and DRPLA, and is rare in SCA6. On the other hand, it is quite characteristic of SCA1, 2 and 7. Cerebral atrophy and compensatory enlargement of the lateral ventricles can be seen in DRPLA, SCA2, and the infantile variant of SCA7.

More expensive imaging studies such as magnetic resonance spectroscopy and positron emission tomography (PET) scanning are sensitive markers for deterioration and show abnormalities beyond the structural changes revealed by MRI scans. Their role, however, is controversial, and at the moment, these modalities should be reserved for research rather than diagnosis.

Most spinocerebellar ataxias cause defects in nerve conduction, especially SCA4. The predominant axonal neuropathy affects mainly sensory neurons, and sural nerve action potentials are commonly absent. Nerve conduction abnormalities, however, are rarely helpful in determining the genetic subclass of the ataxia. On the other hand, visual evoked potentials can be helpful to suggest SCA7, while interictal electroencephalograph (EEG) abnormalities might suggest DRPLA. Although seizures are common in SCA10, interictal EEGs are typically normal.

Genetic testing is the only definitive diagnostic test. A few differentiating features (Table 118-4) may help in suggesting the likely candidates in a stepwise screen. More often, blood is sent out to test for mutations in a battery of genes. So far, this list includes SCA1, 2, 3, 6, 7, 8, 10, 17 and DRPLA, but the number is likely to increase. Online resources e.g. [www.geneclinics.org](http://www.geneclinics.org), are extremely informative.

**TABLE 118-4** A Few Differentiating Features of the Autosomal Dominant Spinocerebellar Ataxias

Distinguishing Features of the Spinocerebellar Ataxias	
SCA1	Relatively nondescript spinocerebellar ataxia with neuropathy and pyramidal signs
SCA2	Slow saccades, myoclonus, areflexia
SCA3	Bulging eyes, fasciolingual fasciculations, extrapyramidal signs
SCA4	Sensory neuropathy
SCA5	Slow course despite early onset
SCA6	Very late-onset, mild, apparently sporadic onset
SCA7	Macular degeneration
SCA8	Mild
SCA9	Unassigned
SCA10	Generalized or complex partial seizures
SCA11	Mild
SCA12	Tremor, dementia
SCA13	Mental retardation
SCA14	Often associated with myoclonus
SCA15	Mild
SCA16	Head tremor
SCA17	Bradykinesia and dementia
SCA18	Mixed sensory and motor neuropathy
SCA19	Dementia, myoclonus and tremor
SCA21	Dementia
SCA22	Dysarthria
SCA25	Sensory neuropathy
SCA26	Slow progression
SCA28	Juvenile-onset with eye movement abnormalities, in some cases pyramidal tract signs, dysarthria, hyperreflexia
SCA29	Early-onset, nonprogressive
SCA30	Hypermetric saccades and minor pyramidal signs
SCA31	Reduced muscle tone, possible associated with sensorineural hearing loss
DRPLA	Chorea, seizures, myoclonus

No effective treatment is available for the SCAs although we generally treat our patients with antioxidants such as vitamin E. Like Friedreich's ataxia a team approach involving physical therapists, occupational therapists, and genetic counselors help advise each individual patient.

## 118.8 EPISODIC ATAXIAS

There are seven varieties of dominantly inherited episodic ataxias called episodic ataxia type 1 (EA1) to episodic ataxia type 7 (EA7) (304). EA1 and EA2 are the most common. Both of these diseases begin in late childhood or adolescence and respond to treatment with acetazolamide.

Patients with EA1 show short episodes of ataxia rarely lasting beyond a few minutes. Ataxic spells sometimes are induced by exercise and may be accompanied by myokymia in the hands and face. Pathology is minimal with mild atrophy of anterior cerebellar vermis. The genetic basis for EA1 is the presence of point mutations in a voltage-gated potassium channel gene, *KCNA1*, located on chromosome 12p13 (305,306). Recently, a mouse model of EA1 has been engineered that should lead to important insights into pathogenesis and possibly even treatment options (307).

In EA2, the attacks are longer, lasting usually for a few hours or even days. Moreover, these episodes appear to result in cumulative damage as patients often go on to develop cerebellar symptoms and atrophy. Thus, subtle cerebellar signs such as nystagmus and mild clumsiness should tilt the diagnosis toward EA2 rather than EA1. As mentioned in the context of SCA6, EA2 is caused typically by mutations in the  $\alpha_{1A}$  subunit of the calcium channel gene, the gene involved in SCA6 and also familial hemiplegic migraine (203,308–310). There is at least one family with a mutation in the gene for the beta-4 subunit of this channel (311). It is possible that mutations in the P/Q-type calcium channel reduce calcium-dependent neurotransmitter release that then triggers ataxia (312). Recently the potassium channel blocker 4-aminopyridine has been shown to reduce the frequency of attacks, presumably by first increasing the excitability of cerebellar Purkinje cells followed by a subsequent release of the inhibitory neurotransmitter GABA (313).

Patients with episodic ataxia type 3 have brief attacks of ataxia, vertigo, tinnitus, and myokymia that have a variable age of onset (314). It appears to be linked to chromosome 1q42 (315), and the attacks are responsive to acetazolamide.

Patients with episodic ataxia type 4 have attacks of vertigo, tinnitus, diplopia, and ataxia beginning in early adulthood (316). Patients often display poor smooth pursuit with respect to their eye movements. They also display gaze-evoked nystagmus (317). EA4 is typically unresponsive to acetazolamide.

Patients with episodic ataxia type 5 display ataxia reminiscent of EA2 with attacks lasting hours (318). EA5 is caused by a mutation in the CACNB4 gene on chromosome 2q22-23 (311).

EA6 is caused by a heterozygous mutation in the SLC1A3 gene, a member of the solute carrier family that encodes the excitatory amino acid transporter 1 (EAAT1) (319). Episodic ataxia can also be associated with seizures, migraine, and alternating hemiplegia.

EA7 has been identified in a single family with clinical features of EA2 except that they do not display persistent cerebellar symptoms with time (320). This gene has been linked to chromosome 19q13.

### 118.9 X-LINKED ATAXIAS

Besides adrenomyeloneuropathy (described earlier), which can present as an ataxic syndrome, there are a few X-linked progressive ataxias. These can be almost purely cerebellar syndromes (321,322) or associated with a wider spectrum of signs such as anemia, deafness, spasticity, or dementia (323–326). In most instances, the genetic loci are still unknown. One X-linked ataxia where the gene has been identified is X-linked sideroblastic anemia with ataxia (ABC7 transporter gene at Xq13) (327). How this defect leads to ataxia is still unclear. Another X-linked ataxia that has been mapped to a locus is the early-onset X-linked ataxia that is characterized by deafness and loss of vision (links to locus Xq21.2–q24) (328). The Fragile X-associated tremor ataxia syndrome (FXTAS) has been described above in the differential diagnosis of the autosomal dominant SCAs.

### 118.10 MITOCHONDRIAL ATAXIAS

Mitochondrial deficits can present with a progressive or intermittent ataxia. For instance, *Leigh syndrome*, a genetically heterogeneous syndrome caused by mutations in several genes affecting mitochondrial function, often presents with an intermittent ataxia and atypical necrotizing encephalitis not unlike that seen in thiamine deficiency. An MRI scan is informative in revealing characteristic subcortical necrotic lesions. Leigh syndrome phenotype has been associated with autosomal dominant, X-linked, or with mitochondrial DNA (maternal inheritance) mutations. Mutations in SURF1, a gene located on chromosome 9q34, have been identified in several COX-deficient patients with Leigh syndrome (329,330).

Leigh syndrome is also often accompanied by cardiomyopathy, presumably because of mitochondrial energy failure in cardiac muscle. Ataxia and myoclonus can also be seen in other defects of the mitochondrial genome. Both larger deletions and duplications characteristic of Kearns–Sayre syndrome and maternally-inherited point mutations in mitochondrial genes encoding tRNA, the MELAS (mitochondrial encephalopathy, lactic acidosis,

and stroke-like episodes), and MERRF (myoclonic epilepsy with ragged red fibers) have been associated with the ataxic phenotype. Historically, these diseases contributed to the Ramsay Hunt syndrome, an ataxic syndrome characterized by myoclonus. Other etiologies of this phenotype include some of the storage disorders described above, in particular sialidosis, but this constellation of symptoms is also seen in *Baltic myoclonus of Unverricht-Lundberg*, an autosomal recessive ataxia, where the underlying defect is in the gene encoding the protease inhibitor cystatin B. This disease is prevalent in Scandinavia and maps to locus 21q22.3 (331). Surprisingly, in most instances, this is also a repeat disorder, but the repeat is a dodecamer repeat in the gene's promoter region. With better genetic delineation, the term “Ramsay Hunt syndrome” will probably become relegated to history, since it does not really throw light on the etiology of a variety of disparate conditions.

### 118.11 CONCLUSIONS

A decade ago, it would have been difficult to predict the rapid advances in our understanding of the genetics of hereditary ataxias. This progress has not been confined to the identification of the genetic basis of individual diseases; we have begun to sort out candidate pathways in pathogenesis, using a plethora of tools from the growing armamentarium offered by present day molecular biology and genomics. The development of animal models, in particular, is now recognized as a notable first step in hypothesis testing and, more importantly, as an approach for testing possible therapies. The various animal models—the mouse, *Drosophila*, *Caenorhabditis elegans* and yeast—offer powerful, complementary tools for elucidating complex pathways at the level of the whole organism.

An excellent example that validates such an approach has been the dissection of the chaperone and ubiquitin-proteasomal pathway in polyglutamine disease. Initial work on this pathway in transfection experiments has found confirmation in genetic screens in the fly, where overexpression of heat shock proteins can rescue a polyglutamine-induced phenotype (332–334). Another example has been the pivotal role of yeast in elucidating the role of the oxidative stress induced by the mitochondrial accumulation of iron (49). In the prevailing climate of combinatorial chemistry and rational drug design, we anticipate high-throughput screens for chemical modifiers using simple animal models. Using such techniques, pharmaceutical companies could potentially identify candidate agents that can then be tested as therapeutic agents first in animal models and then in the human patient. Currently, there are clinical trials testing the role of agents that modulate synaptic activity (riluzole and varenicline), antioxidants such as coenzyme Q10, and lithium for ataxia treatment. Other strategies being tested include RNA interference or micro-RNA-based

mechanisms to shut down gene expression of mutant proteins. Thus, for the patient, there is reason for hope, even though the desired outcome of actual therapies remains to be seen. For the present, genomics and web-based dissemination of information have already wrought changes in the way patients view their chronic diseases. They are better informed about the genetics of transmission and disease prognosis and are therefore in a better position to plan their lives. In return, they are often more willing to provide blood samples for DNA analyses and enroll in variety of clinical trials that are crucial for clinical progress. The National Ataxia Foundation ([www.ataxia.org](http://www.ataxia.org)) and nonprofit organizations such as [www.wemove.org](http://www.wemove.org) are playing important roles in educating patients and the larger public.
